3. Vertical spindle ring and surface grinding machine, where the grinding wheel is of cup form, carried on a vertical spindle, and the work is carried on a circular rotating table, generally in the form of a magnetic chuck and rotated under the wheel.

4. Vertical spindle surface grinding machine, where the wheel is of cup form carried on a vertical spindle, and the work is carried on a table reciprocating under the wheel.

The first and fourth types are the most commonly used, and intended for the grinding of flat surfaces of all kinds and in all materials.

The second and third types are widely used for grinding the sides of disc work, such as circular knives and saws, piston rings, disc valves, etc., using the rotary table. The second type of machine with the horizontal spindle leaves the work with a concentric finish, whereas the third type of machine with the cup wheel leaves the work with a radial finish, and which in some classes of work is objectionable, particularly, for instance, in piston rings, where the concentric finish is preferred. So far as production is concerned the vertical spindle ring and surface grinding machine will give a greater output than the horizontal spindle ring and surface grinding machine. Both machines can be arranged to grind flat, concave, or convex surfaces.

The most largely used machine for regular commercial purposes is the machine with the vertical spindle, owing to its greater productive capacity.

The best *wheel speed* for all-round surface grinding is about 4,000 ft. per minute, with very little margin of speed—that is, if a wheel is working successfully at 4,000 ft. per minute, it cannot be varied up or down from this speed without affecting production, consequently the vertical spindle machine with the cup wheel has a great advantage in this respect, due, of course, to the wheel retaining its diameter as it wears.

The grade of the wheel for surface grinding demands far closer attention than in any other type of grinding. The only remedy for a wheel that is too hard or too soft is to change it for a wheel of the correct grade.

A high *table speed* is the main factor governing output, using suitable grinding wheels, but the machine which will so work that the temperature is even throughout the whole ground surface will produce the most accurate results.

The vertical surface grinding machine with the cup wheel, which covers the full width of work at each stroke of the table, has a distinct advantage over the horizontal spindle machine using the periphery of the wheel, and which would have to be traversed transversely in order to cover a work surface wider than the width of wheel.

Quite apart, however, from the question of heat distribution, the vertical spindle machine has the greater productive capacity, and for grinding wide surfaces or groups of small articles this type of machine has the advantage of the horizontal spindle machine. The vertical surface grinding machine is now being adopted in all classes of engineering works, and wherever flat surfaces have to be produced, such as in machine-tool work, there is no method that can be compared with it for cheapness of production.

A machine of this type added to the equipment of any works, and used for the production of flat surfaces has, more than any other type of grinding machine, a beneficial effect throughout the works, and in this respect raises automatically the standard of work produced. In this way, given an accurate machine, it is so very easy to true up straight edges and similar tools and keep them all in a constant high state of perfection; and by having a machine of this type always in readiness to produce flat surfaces the result is that more accurate work is automatically produced throughout the works.

The *time required* for grinding a given surface can be ascertained with fair accuracy once a basis is found, based on area ground and amount of metal removed. Under normal working conditions, a grinding wheel has a certain capacity for the removal of metal, based on its cutting area or its diameter and width.

Examples of Grinding.

The following examples will serve to show what may be expected from wheels which are suited to the conditions and work in hand :—

A batch of 72 soft steel spindles of diameters ranging from 1½ inch down to $\frac{9}{16}$ inch by 8 inches long, and having from ·010 to ·015 inch left for grinding, were finished in an average time of 4½ minutes each. The wheel was Norton 'Alundum' 60.M, running at a speed of 6,500 ft. per minute, and it lost ·0005 inch diameter for every six spindles ground. The work speed was 30 ft. for $\frac{9}{16}$ diameter, and 60 ft. for 1½ inch diameter, and the grinding limit was ·00025 inch.

Cast-iron spindle tubes 2½ inches diameter by 12 inches long took an average time of 10 minutes each to finish. The grinding limit was ·00025 inch, and the amount removed ·010 to ·015 inch. The wheel was Norton 'Alundum' 46.H, running at 5,500 ft. per minute, and it lost ·001 inch in diameter on every tube. The speed of the work was 30 ft. per minute.

These examples are given as indicating an amount of reduction in wheel size which should not be exceeded under ordinary conditions. *(Churchill Machine Tool Co. Ltd.)*

Grinding Allowances.

(For Norton and Heald Grinding Machines.)

Frequent inquiries as to the amount of stock which should be left on turned and bored work to be ultimately finished to size by grinding had led to the answer that this depends on several factors which must be ascertained before a correct allowance can be determined. The object aimed at should be to so proportion the work between the lathe and the grinding machine that the total time taken by both in producing the desired degree of finish and accuracy is reduced to the minimum.

In a desire to turn out a 'good job' the turner sometimes overlooks the fact that a smooth piece of work having only a small allowance may take as long to finish in the grinding machine as a rough-turned job on which more metal is left.

The chart, fig. 8, shows the grinding allowances which are recommended for turned or bored work up to 12 ins. diameter. Although the amounts specified may, to some, appear excessive, they may be allowed with confidence in establishments possessing a grinding department run according to modern ideas of efficiency and lathes sufficiently powerful to take the coarse feeds recommended.

Curves A and A¹ show maximum and minimum amounts to be left on the diameter of rough turned work over 12 diameters long.

Curves B and B¹ show maximum and minimum amounts to be left on the diameter of rough turned work under 12 diameters long.

Curves C and C¹ show maximum and minimum amounts to be left on diameter of smooth turned and bar-lathe work over 12 diameters long.

Curves D and D¹ show maximum and minimum amounts to be left on diameters of smooth turned and bar-lathe work under 12 diameters long.

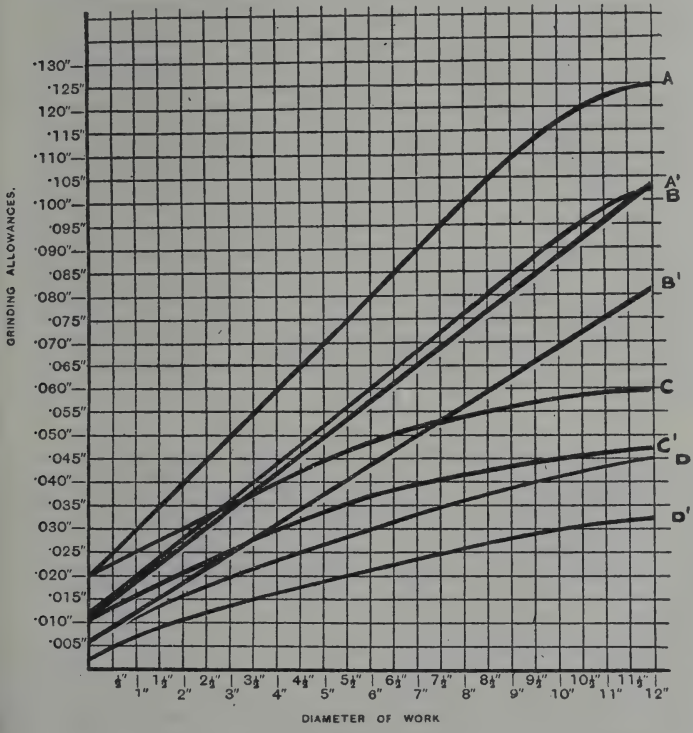

FIG. 8.—Grinding Allowances for Norton Cylindrical Grinding Machines.

NOTE.—By 'rough turned,' is meant work having coarse traverse marks, the measurements being taken on the top of the ridges. The following are the finest feeds which should be employed :—

For work up to 2 ins. diameter	30 per inch
For work from 2 ins. to 4 ins. diameter	20 ,,
For work from 4 ins. to 8 ins. diameter	16 ,,
For work from 8 ins. to 12 ins. diameter	8 ,,

T T

Case-hardened work is an exception, because the finish must be fairly smooth to allow regular penetration of the casing compound. Use curves C and C¹ for all such work.

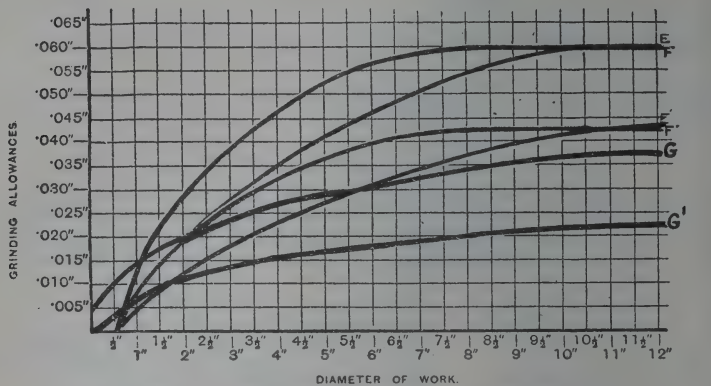

FIG. 9.—Grinding Allowances for Heald Internal Grinding Machines.

Curves E and E′ (fig. 9) show maximum and minimum amounts to be left in the bore of mild steel work that is to be case-hardened before grinding.

Curves F and F¹ show maximum and minimum amounts to be left in the bore of carbon or high-speed steel work that is to be hardened before grinding.

Curves G and G¹ show maximum and minimum amounts to be left in the bore of soft work, whether steel, cast iron, or brass.

NOTES.

The following explanatory notes will serve to show the theory followed out, and will assist in determining allowances for the exceptional jobs which will occasionally present themselves :—

Taking first *external work*, as being the more common, it will be noted that a larger allowance is made on articles which exceed twelve diameters length than in the case of shorter jobs. This is to save lathe work.

A job over twelve diameters long will spring considerably under a good cut, and there is a possibility of bends making their appearance. The largest possible allowance is therefore made on this work, so that the turner need not waste the time which would be taken in producing articles more nearly parallel and straight.

Then, again, a distinction is made between rough-turned work and that which is produced by a fine feed or made on turret lathes with a box tool.

For all work turned between centres, with the exception of that which is to be carbonised for case-hardening, the use of a coarse traverse is advocated, the finest feed per inch that should be used for various diameters being specified on the chart. Work which is to be carbonised must be turned with a fairly smooth finish, so as to allow regular penetration of the casing compound ; therefore the allowance specified for smooth work over twelve diameters long should be used for case-hardened work whatever its length. If such work is holiow it may distort after quenching, therefore great care must be exercised in hardening, as the allowance above specified cannot be exceeded or the hard skin would be entirely removed in grinding to size.

The allowance for carbon and high-speed steel work which is hardened will be the same as that provided for soft work, as any distortion which occurs must be corrected in the straightening press before grinding.

Internal work, which is dealt with by the lower portion of the chart, is divided into three classes as follows :—

1. Mild steel case-hardened.
2. Carbon or high-speed steel hardened.
3. Soft work, whether steel, cast iron, or bronze.

Hardened and case-hardened work in which the hole is less than half an inch in diameter should, as shown in the chart, be bored or reamed to standard size, as there will be a sufficient

shrinking when the quenching takes place to provide a grinding allowance. It will be noted that the amount allowed in case-hardened work increases very rapidly up to 6 ins. diameter; this is to allow for distortion in hardening. Above this size the increase is slow, and care should be taken to avoid excessive distortion, as no larger allowance can be made, otherwise the hard skin would be removed by the grinding operation. In determining the allowance for soft work it should be remembered that the class of finish given to the hole will decide whether the high or low limit should be worked to. Thus, in holes which are rough drilled or bored, the allowance should approach the maximum, whilst in reamed holes the minimum allowance should be left.

(*Alfred Herbert Ltd., Coventry.*)

Polishing.

For grinding and polishing *marble*, *stones*, and *glass*, crushed steel has proved very satisfactory, on account of its hardness, sharpness and toughness. It is, however, but little used in this country, sand, carbide, or aluminous abrasives being generally employed. For cutting stone, marble, and glass, a metal wheel with loose sand and water is largely employed, but grinding wheels of carbide and aluminous abrasives of medium grade and 36–50 grit are being increasingly employed. For producing a rough surface on glass, the sand-blast process is largely used.

For *smoothing wood* and similar materials, garnet-emery and sand, mounted on paper or cloth, are largely employed, garnet being especially suitable for hard woods. For finishing wooden handles, sand mounted in endless belts is largely used.

In the leather industries, and especially in the manufacture of boots and shoes, corundum and carborundum cloths are largely used for heel scouring and breasting and for buffing.

For work in which an *exceptionally hard abrasive* is required, including the truing of abrasive wheels, diamond bort or carbonado are employed.

For polishing steel articles, blocks of carbide or aluminous abrasive or cloth or paper covered with emery or corundum is largely employed.

For polishing other metals, glass, etc., loose powders are employed. Such powders may be used in the dry or wet state, and may be rubbed on to the material to be polished, or they may be applied by means of a wheel (or 'dolly') composed of discs of cloth.

For polishing brass and other softer metals, very fine silica, quartz flour, emery carbide or aluminous abrasives, crocus, rouge, or whiting are employed. For silver and gold well-slaked lime is largely used. The polishing powder is sometimes treated with rouge to disguise its nature and to give white metals a slightly ruddy tint, which improves their appearance.

In the so-called liquid polishes, a little oxalic acid or other chemical detergent is sometimes added to the abrasive powder, or to the liquid in which the latter is suspended.

Power required for Emery Polishing.

Using a calico mop, 12 ins. diameter by 2 ins. wide, it is usual to run these at a speed of 10,000 feet per minute. The average resistance at the circumference of a well-loaded wheel is about 10 lbs., and this would give a h.p. for the mop equal to 3. To this has to be added the friction of the spindle in its journals, and this will depend on the nature of the journal (whether plain or ball), and also the lubrication. The friction is principally due to the pull of the strap, and if its spindle is taken to be $1\frac{1}{2}$ in. diameter, and the value $\mu = \cdot 075$, the frictional h.p. would be about ·25, and if a further ·25 be allowed for acceleration, the h.p. to drive the machine would be $3\frac{1}{2}$. For a 10 in. diameter buff the h.p. would be proportionately less—that is, about 3.

Sand Blasting.

The air pressures used for different materials are, approximately, as follows:—Steel castings or forgings, 80 to 100 lbs.; malleable iron, 70 to 85 lbs.; cast iron, 60 to 70 lbs.; and brass and aluminium, 35 to 50 lbs.

For some classes of work a small nozzle opening, that is, a fine strong jet, may be desirable; for other work a broader stream, covering a larger surface but working at a lower pressure may be best. Table I. gives the relation between air flow in cubic feet of free air per minute at varying pressures, and the horse-power required to produce them by single-stage compression, for nozzles ranging in diameter from $\frac{1}{8}$ to $\frac{3}{8}$ in. inclusive.

Typical cylinder dimensions, together with the displacement and the horse-power required to develop various amounts of air pressure, are given in Table II.

In cases where there is moisture in the air, it is well to make provision for the elimination of the moisture by installing a moisture separator or a suitable heater.

Sand is the most commonly used abrasive on account of its relatively low price. Ordinary sand is inferior to sea sand and silica sand, as the two latter possess greater hardness and are therefore more lasting. Abrasives such as steel grit and shot are used to a certain extent, and the use of these more expensive abrasives is warranted under certain conditions. For classes of work such as electro-plating or galvanising, the metallic dust adhering to the work would make its use prohibitive, because it prevents perfect galvanising, although no difficulty is experienced in this respect with sand.

There is no one abrasive that is best adapted to all classes of work. A selection must be made with due regard to reclaiming means, to greatest economy in operation, and to maximum production. By making tests with various materials, and keeping accurate records of quality of work, output, life of the abrasive, and so on, the one best suited for the individual application is readily determined. Such tests have shown metal abrasives to have about sixty times the life of sand. This apparently large percentage may, however, be offset to a great extent by losses of abrasive in operation or in handling. In good steel foundry practice these losses may be kept as low as 10 per cent., while the average loss due to disintegration, for different grades of sand, amounts to about 20 per cent. per month. The reduction in cleaning time resulting from using metal abrasives instead of sand varies, of course, but a gain of about 15 to 20 per cent. in time appears to be in line with actual practical experience. Metal abrasives do not require large sand-storage bins and have the added advantage of producing less dust, thereby improving the general working conditions.

12	12	220	340	45	50·0	54·0	58·0	62·0	65

All abrasives should be screened each time before using, to remove particles large enough to clog the nozzle, and also to eliminate fine particles which only produce dust and have no abrasive quality, but which consume some of the pressure. Screen separators, frequently operated by compressed air, may be used for this purpose. (*Abstract, C.M.S., 'Machinery,' Jan.* 13, 1921.

SECTION XXI

PART III

STEAM-HAMMERS.

(*Messrs. B. & S. Massey, Ltd., Openshaw.*)

Three standard types of steam-hammer are made by B. & S. Massey, Ltd.—the 'Overhanging Form with Slides,' the 'Arch Form with Slides,' and the 'Rigby type without Slides.' All these hammers can be made suitable for driving by compressed air instead of steam.

Overhanging Form with Slides.

These hammers (fig. 1) are usually preferred for general smith-work. The anvils are accessible to the workman from three sides, and the tups are supported and accurately guided by the slides making it possible to do accurate stamping in dies.

Each hammer has two separate standards, with a space between them, through which long bars can be passed. All the hammers are double-acting and are fitted with equilibrium working valves.

Up to and including the 12-cwt. size, the hammers are fitted with a combined self-acting and handworked valve gear; the 15-cwt. and larger sizes are ordinarily fitted with Massey's Handworked Expansion Valve Gear, but a combined self-acting and handworked gear can be fitted if desired.

The pistons, which are forged solid with the piston-rods, are fitted with steel piston-rings. The palletts are made of tough forged steel with planed and hardened faces.

The anvil blocks are about 8 times the weight of the falling mass, and in the 12 cwt. and smaller sizes they are turned to fit the bored baseplates; this greatly increases the efficiency of the hammers when it is desired to use them for stamping in dies.

†Approximate steam consumption (lbs. per hour)—					
(*a*) On hard blows	1040 lbs.	1190 lbs.	1420 lbs.	1750 lbs.	2100 lbs.
(*b*) Average on mixed blows	170 lbs.	195 lbs.	228 lbs.	275 lbs.	330 lbs.

* All these figures are necessarily rough approximations.

They are meant to apply to average engineers' smithwork, and are for efficient results on this class of work, with a steam pressure of about 60 lbs. per sq. in.

Even for this they may for occasional jobs be considerably exceeded.

There are many classes of work which require much larger hammers, and some classes which require smaller hammers than those indicated, owing chiefly to the varying amount which has to be done at a heat.

† Steam Consumption.

A steam pressure of about 60 lbs. per sq. in. is assumed.

During ordinary forging there are many blows of less than full force, and there are also necessary pauses (holding up) for adjusting work or tools during a heat.

While line (*a*), page 1194, gives the consumption on continuous hard blows only, line (*b*) gives the consumption as ordinarily reduced by these circumstances. Further, under average smithy conditions, a hammer may be assumed to be actually in motion about 15 minutes in every hour, and the figures given in line (*b*) are based on this assumption.

In cases in which one boiler is put down solely to drive one hammer, the capacity of such boiler should be fixed according to line (*a*), page 1194, because otherwise the pressure would fall too low during a normal run of hard blows.

Arch Form with Slides.

These hammers, fig. 2, are made in sizes ranging from 3 cwt. to 10 tons and over, and the design provides a maximum of strength and rigidity. The 15 cwt. and larger sizes are fitted with Massey's Handworked Expansion Valve Gear.

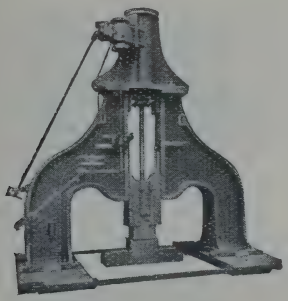

Fig. 2.—Arch Form.

Rigby Type without Slides.

These hammers, fig. 3, which are made in sizes from 3 cwt. to 3 tons, are particularly suitable where forgings of large size and awkward shape have to be dealt with. The strokes are longer

Fig. 3.—Rigby Type.

and the cylinders larger in diameter than in the other forms described. All sizes are fitted with Massey's Handworked Expansion Valve Gear.

Energy and Velocity of Blow.

If

a = area of piston, in square inches : p = average pressure of steam on piston during downward stroke, in pounds per square inch : S = stroke of piston, in feet : W = falling weight in pounds : E = energy of blow after full stroke and before striking, in foot-pounds, friction being neglected ;

$$E = (ap + W)S.$$

If

P = total pressure on piston = pa : F = total force causing downward acceleration = $P + W = pa + W$: g = acceleration due to gravity = 32·2 : V = velocity after full stroke and before striking, in feet per second, friction again being neglected ;

$$V^2 = \frac{2Fg S}{W}.$$

No commercial use is made of these calculations, either for the naming of sizes of hammers or for any other purpose.

The question is sometimes asked : *What weight of blow does the hammer strike ?*

The force of a blow cannot be stated in terms of weight at all, because the pressure of a weight is continuous, whereas the force of a blow is expended in a moment. It has, however, been ascertained, by careful experiments, that the maximum blow of a 5-cwt. double-acting steam-hammer, with moderate steam pressure, produces a crushing effect upon a piece of hot iron as great as that produced by a load of about 30 tons, and a ¼-cwt. double-acting steam-hammer a crushing effect equal to that produced by a load of about 2½ tons.

Naming Sizes of Steam-Hammers.

In naming the sizes of steam-hammers, no account is taken of the pressure of steam upon the piston. Thus, a 5-cwt. hammer is one in which the falling mass weighs at least 5 cwt., but of course the force of the blow is greatly increased by the pressure of steam above the piston accelerating the fall.

Steam Pipes for Steam Hammers.

See 'Steam Pipe Bends,' Section XXX, Part II.

Foundations.

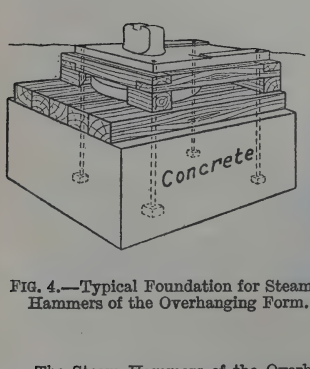

Fig. 4.—Typical Foundation for Steam-Hammers of the Overhanging Form.

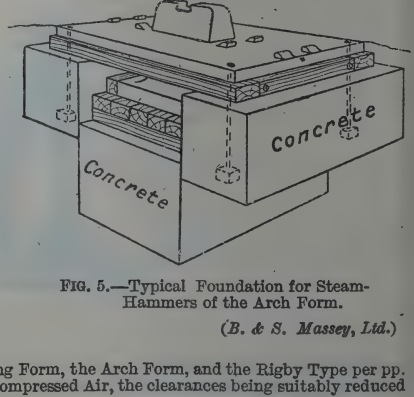

Fig. 5.—Typical Foundation for Steam-Hammers of the Arch Form.

(*B. & S. Massey, Ltd.*)

The Steam Hammers of the Overhanging Form, the Arch Form, and the Rigby Type per pp. 1193-1195 can all be driven equally well by Compressed Air, the clearances being suitably reduced

PNEUMATIC POWER HAMMERS.

Massey Patent Pneumatic Power Hammers, Overhanging Form with Slides.

These hammers (fig. 6) are arranged for belt or for direct electric drive. They are similar to steam-hammers in many respects, and are about equal to them in working capacity, assuming the steam-hammers to be working under ordinary conditions of pressure, etc.

It is very important to note that the size name of each hammer indicates the true weight of its falling parts.

The anvil block is set diagonally, to enable long bars to be worked in either direction.

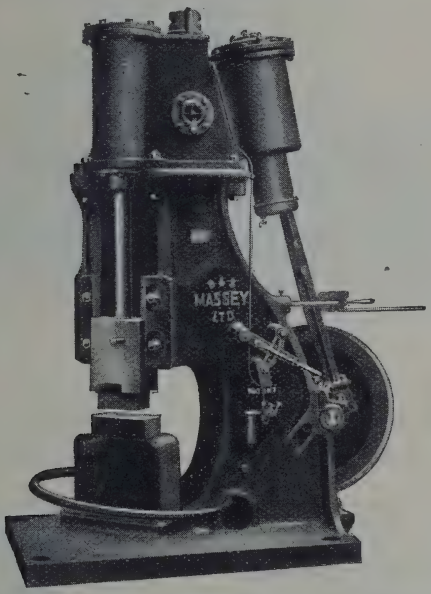

Fig. 6.

The essential feature of the hammers lies in the connecting together of two cylinders—the hammer cylinder and the pump cylinder—by air passages which are governed by a valve under the control of the operator. See fig. 7, p. 1198.

When the piston reciprocates with the valve in the 'not working' position (as shown) air flows freely through the valve from one side of the piston to the other. The tup therefore remains stationary on the anvil.

As the valve is moved upwards the by-pass through the valve is gradually closed, so that when position 4 is reached, all the air is forced from the top of the pump to the top of the hammer, and from the bottom of the pump to the bottom of the hammer, thus producing full-force automatic blows. The positions intermediate between 3 and 4 provide a wide variation in the character of blow and the length of stroke.

With the valve in position 1, the reservoir is charged from the top and bottom of the pump and is, at the same time, in communication with the bottom of the hammer. This gives a perfectly smooth rise and a steady 'Hold-up.'

When the valve is moved to position 2, the bottom of the hammer is opened to atmosphere, and compressed air from the reservoir passes into the top, thus throwing down the tup and striking a single blow.

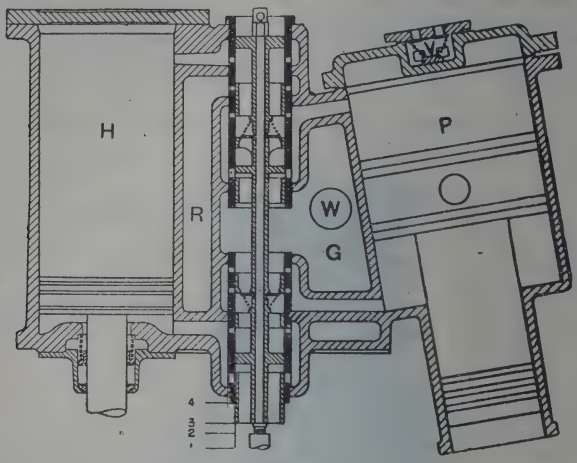

FIG. 7.

While the valve is kept in this position, the tup is held down with full pressure above the piston.

Inlet valves V and W supply air to the top and bottom of the system.

Massey Patent Pneumatic Power Hammers.

Arch Form with Slides.

These hammers, fig. 8, are made in the 30 cwt. and 40 cwt. sizes, and are arranged for 'direct electric drive.' The action and control of the hammers is identical with that of the overhanging

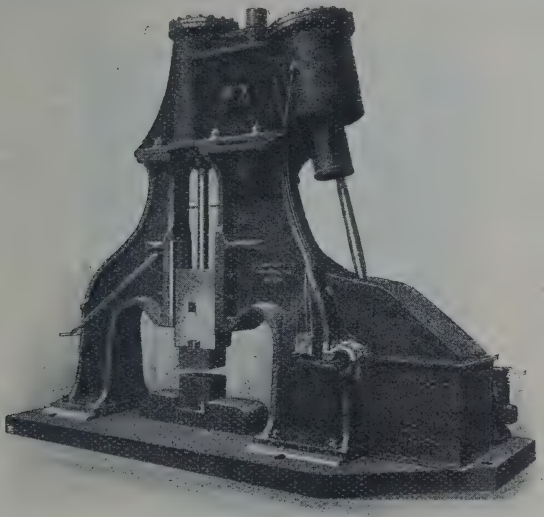

Fig. 8.

form with slides (pp. 1197-98), *i.e.* 'Single Blows' may be struck from any point in the stroke, each requiring a separate movement of the hand lever, or a series of automatic blows may be obtained of any desired force and with long or short strokes.

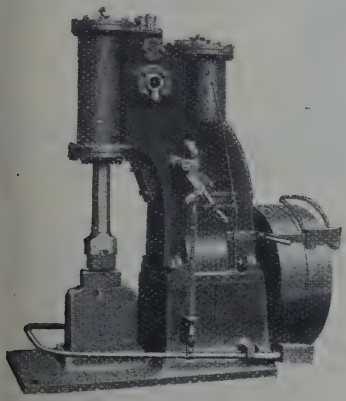

Fig. 9.

'Clear Space Type without Slides.'

These hammers also are identical in action and control with the hammers of the overhanging form with slides (pp. 1197–98). As will be seen from fig. 9 ample clear space is provided for the manipulation of large and awkward forgings, by dispensing with Slides and adopting a special Stuffing Box to guide the rod.

The hammers can be belt or motor driven, and provided with a foot lever in addition to the hand lever, if desired.

DROP STAMPS.

The Massey Friction Drop Stamp

The practice of Stamping, in Dies, parts which have to be made in large numbers, such as motor-car parts, railway wagon parts, etc., etc., has become very general, and the tool usually adopted

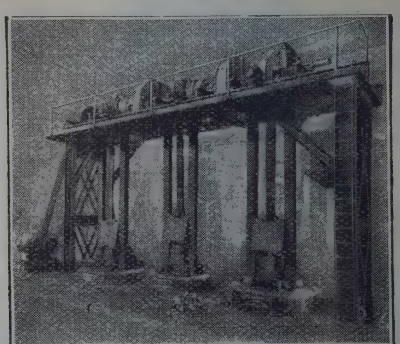

Fig. 10.—Battery of 30-15-20 cwt. Friction Drop Stamps.

for this purpose in this country is the 'drop stamp.' Latterly, the friction lifted type of drop stamp (fig. 10) has tended to supersede the steam lifted type, on account of the improved control, the greater efficiency and the smaller cost of up-keep.

General Construction.

The usual plan is to have two, three, or four drop stamps of different falling weights arranged in a battery. The lifting mechanism in this case is mounted on girder work supported on stanchions, while the falling weight or tup is guided by vertical rolled steel guides resting in recesses in the anvil block, and supported at their upper ends by the girder work in such a way as not to transmit shock to the lifting mechanism.

Details of Friction Lifters.

The lifters themselves resemble a band brake in construction. A steel brake band lined with suitable material, and connected with the lifting arm, is made to grip a constantly revolving drum by means of a lever actuated by hand through a pulling cord, and the tup is thereby raised. As soon as the tension on the cord is released, a spring disengages the band, and the tup falls under the influence of gravity.

A special arrangement is adopted by means of which the grip of the friction band is automatically reduced as the tup rises, thereby making it necessary to maintain a constant pull on the cord in order to prolong the rise of the tup; when, moreover, the cord is held stationary, the tup remains suspended at the point to which it may have been raised, and as stated above, the tup falls when the tension on the cord is released.

It will therefore be seen that a very intimate relation exists between the movements of the tup and those of the pulling cord.

The movement of the hand is only a short one, and the pull required is very slight, but every movement of the hand is reproduced on a larger scale by the tup. Those who are familiar with the old-fashioned kick stamps in which a heavy pull was required the whole length of the

stroke, and which sometimes required two or three men to act as pullers, appreciate very highly the action of friction stamps in which a control as excellent as in the kick stamp is secured with so little labour on the part of the operator.

Method of Driving

The friction lifters are generally mounted on shafts driven by spur gearing from a quick-running back shaft. A flywheel which also serves as a driving pulley is mounted on one end of the back shaft and supplies the reserve of power needed at the moment of picking up the tup.

The drive is usually taken direct from an electric motor placed either on one of the stanchions or in the larger sizes on the floor, or in some other convenient position.

THE MASSEY PATENT AUTOMATIC FRICTION DROP STAMPS.

Although it is usual to arrange the friction drop stamps referred to above in batteries, they can, if desired, be made of the self-contained form, and certain sizes of this type can be fitted with the 'Massey' Patent Automatic Lifting Gear.

This gear (fig. 11) combines the principles of the ordinary friction drop stamps with an automatic action obtained by means of a clutch arrangement controlled by cams, the friction band gripping and releasing the drum alternately at the bottom and top of the stroke.

By means of two hand levers the action of the controlling cams can be advanced or retarded, the length of the stroke and the character of the blow being thus altered at will to suit the nature of the work.

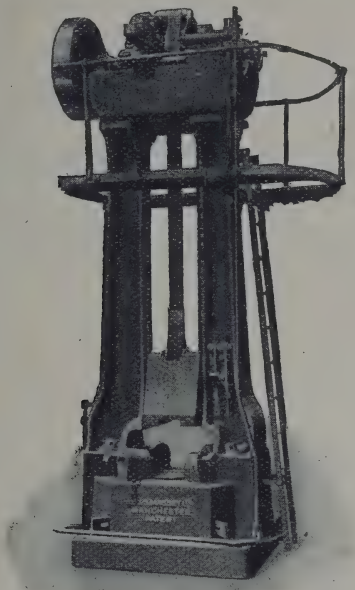

FIG. 11.

By moving these hand levers to their lowest possible positions, the automatic gear can be put out of action entirely, and the stamp worked by hand in the ordinary way.

The tup can be held suspended at any point by means of a friction hold-up gear actuated by a foot lever, and as this gear is independent of the rotating shaft, no power is consumed in holding up.

When the automatic gear is in use, the hold-up gear comes into action as soon as the foot lever is released, and the tup at once rises to the top of its stroke wherever this may have been set, and is held suspended there.

SECTION XXII

SCREW THREADS AND SCREWS—BOLTS AND NUTS—LOCK NUTS—SPANNERS—PIPE FLANGES—KEYS—SCREW TAPS—COUPLINGS—PULLEY ARMS AND BOSSES.

(Revised by Professor Dempster Smith, M.B.E., M.Sc.Tech., M.I.Mech E.)

SCREW THREADS AND SCREWS.

Forms of Screw Threads.

Figs. 1, 2, 3, and 4 show four usual forms of thread, each of 1 inch pitch.

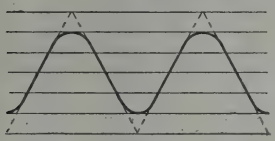

FIG. 1. Whitworth Thread-form.

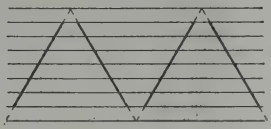

FIG. 2. American Thread-form.

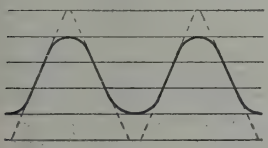

FIG. 3. Swiss Thread-form.

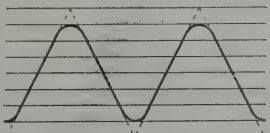

FIG. 4. Steinlen Thread-form

In the *Whitworth* or *English Standard* thread (fig. 1) the angle made by the two sides of the thread is 55° for all sizes of thread. One-sixth of the depth of the triangle is rounded off the top and bottom, so that the angle of 55° gives for the actual depth rather more than three-fifths and less than two-thirds of the pitch.

In the *American* (*Sellers'*) thread (fig. 2) the angle made by the two sides of the triangle is 60°, and one-eighth of the depth is cut off the top and bottom of the triangle, leaving a flat one-eighth of the pitch in width.

In the *Swiss* or *Thury* thread (fig. 3) the angle made by the two sides of the thread is 47½° and one-fifth of the depth is rounded off the top and bottom of the triangle.

For screw-plate Swiss threads the depth of the thread is three-fifths the length of the pitch.

The top of the ridge is formed by a circular arc (*a*), the radius of which equals one-sixth of the pitch. The space between two consecutive ridges is formed at the side next the core by a circular arc (*b*), the radius of which equals one-fifth of the pitch.

The Swiss thread for screws made in the lathe is the *Steinlen* thread (fig. 4). The angle made by the two sides of the thread is 58° 8′, and the radius of the connecting arcs is ·1011 of the pitch. The generating figure is an isosceles triangle, of which the base and the height are equal to the pitch. One-eighth of the depth is rounded off the top and bottom of the triangle.

The *British Association* thread is similar to that of Thury, except that the top and bottom of the threads are both rounded to the same radius, namely, two-elevenths of the pitch.

BRITISH STANDARD FINE (B.S.F.) SCREW THREADS AND THEIR TOLERANCES.*
(No. 84—1918.) (*Abstract.*)

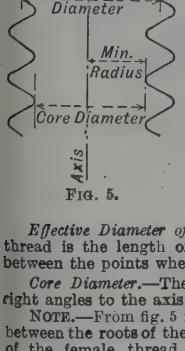

FIG. 5.

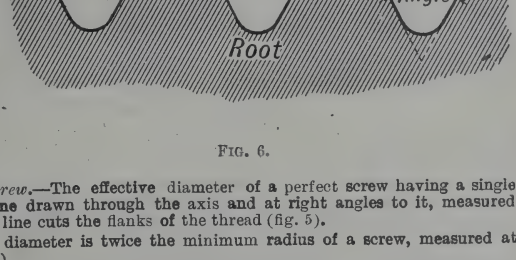

FIG. 6.

Effective Diameter of a Screw.—The effective diameter of a perfect screw having a single thread is the length of a line drawn through the axis and at right angles to it, measured between the points where the line cuts the flanks of the thread (fig. 5).

Core Diameter.—The core diameter is twice the minimum radius of a screw, measured at right angles to the axis (fig. 5).

NOTE.—From fig. 5 it will be seen that the 'core diameter' of the male thread is measured between the roots of the thread; it should be borne in mind, however, that the 'core diameter' of the female thread, being approximately the same dimension, is measured between the crests of the thread.

Full Diameter.—The full diameter is twice the maximum radius of a screw, measured at right angles to the axis (fig. 5).

Crest.—The crest is the prominent part of the thread, whether of the male screw or of the female screw (fig. 6).

Root.—The root is the bottom of the groove of the thread, whether of the male screw or of the female screw (fig. 6).

* By permission of the British Engineering Standards Association.

Flank of Thread.—The flank of the thread is the straight part of the thread which connects the crests and roots (fig. 6).

Angle of Thread.—The angle of the thread is the angle between the slopes, measured in the axial plane (fig. 6).

Pitch.—The pitch is the distance in inches or millimetres measured along a line parallel to the axis of the screw between the point where it cuts any thread of the screw and the point at which it next meets the corresponding part of the same thread (fig. 6). *The reciprocal of the pitch* measures the number of turns per inch or millimetre, as the case may be.

RECOMMENDATIONS.

Form of Thread.

1. The Association recommend that the Whitworth form of thread, as defined in clause 2, be adopted on all screws of $\frac{7}{32}$ in. diameter and above, having British Standard Fine Pitches.

Definition of Whitworth Form of Thread.

2. The following defines the Whitworth thread :—

The *Whitworth Form of Thread* is one in which the angle between the flanks, measured in the axial plane, is 55° ; one-sixth of the sharp triangle is truncated at top and bottom, the threads being rounded equally at crests and roots to a radius which is therefore 0·137329 times the pitch ; the depth of the thread is 0·640327 times the pitch.

TOLERANCES.

—	Full Diameter.	Effective Diameter.	Core Diameter.
Bolt	$3\times\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$	$4\times\cdot01\sqrt{p}$
Nut	$4\times\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$	$3\times\cdot01\sqrt{p}$

The corresponding tolerances on grade and play are :—

$$\text{Grade}=4\times\cdot01\sqrt{p}\ ;\quad \text{Play}=2\times\cdot01\sqrt{p}.$$

In addition, a uniform allowance of 2 thousandths of an inch has been made throughout between the maximum bolt and the minimum nut.

For much work the above tolerances are too large. A second series of tables have therefore been formed by halving the tolerances everywhere. The Association recommend that threads made in accordance with these dimensions be known as ' British Standard Fine Threads (Close Fits).'

The basis of calculation of these tolerances is given below.

—	Full Diameter.	Effective Diameter.	Core Diameter.
Bolt	$1\cdot5\times\cdot01\sqrt{p}$	$\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$
Nut	$2\times\cdot01\sqrt{p}$	$\cdot01\sqrt{p}$	$1\cdot5\times\cdot01\sqrt{p}$

The corresponding tolerances and allowance are :—

$$\text{Grade tolerance}=2\times\cdot01\sqrt{p}\ ;\quad \text{play tolerance}=\cdot01\sqrt{p}\ ;\quad \text{allowance}=0\cdot002\text{ in.}$$

The pitches given in the following table are based on the following formulæ :—

For sizes up to and including screw threads of 1 inch diameter, $P=\frac{\sqrt[3]{d^2}}{10}$.

For sizes above 1 inch diameter, up to and including screw threads of 6 ins. diameter, $P=\frac{\sqrt[3]{d^2}}{10}$

$$\text{Pitch}=\frac{1}{\text{No. of threads per inch}}\ ;\ \text{depth of thread}=0\cdot640327\times\text{pitch}\ ;$$

$$\text{Rounding at crest and root}=0\cdot137329\times\text{pitch}.$$

British Standard Brass Thread.

This is a pipe thread system adopted for thin brass tubing, gas burner fittings, and general brass work; it has a Whitworth thread of a constant pitch of $\frac{1}{36}$-in., or 26 threads per inch.

Comparison of U.S. Standard and Whitworth Screw Threads.

The difference in form that exists between the Whitworth and the U.S. standard screw thread is shown in fig. 7. The comparison is based upon a screw with 1 thread per inch. Clearances and interferences for the two forms of threads having any other pitch may therefore be obtained by dividing the respective values given in the diagram by the number of threads per inch under consideration.

In order to fit a U.S. standard screw into a Whitworth tapped hole or nut, round the outside corners of the screw and change the outline of the thread below the pitch line by slightly filing the flanks. These changes are indicated in the figure by the sectional areas. If it is desired to fit a Whitworth screw into a U.S. standard tapped hole or nut, drill out the hole or nut, using a drill which is larger than the tap drill required for an equal size U.S. standard tap, as shown by

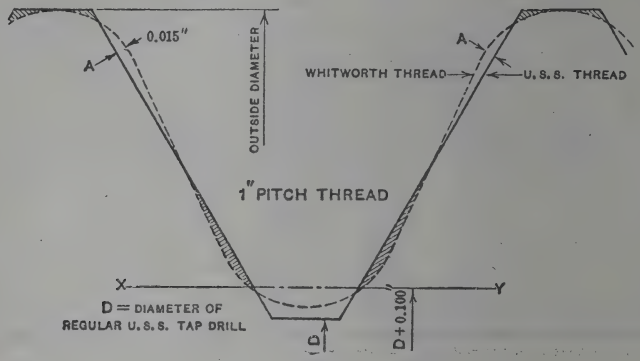

FIG. 7.

the line XY in the diagram. For 1 thread per inch, this increase in diameter of the tap drill will be 0·100 inch, and for other numbers of threads the amount of increase will be found by dividing 0·100 inch by the number of threads per inch. Thus, for 10 threads per inch, 0·100 ÷ 10 = 0·010 inch. The flanks of the Whitworth thread above the pitch line are then filed slightly as indicated at A in the illustration.

The methods mentioned are recommended only for fastening screws and ordinary threaded parts, and should not be employed where accurate threads are required.

INTERNATIONAL SYSTEM OF METRICAL SCREW THREADS.

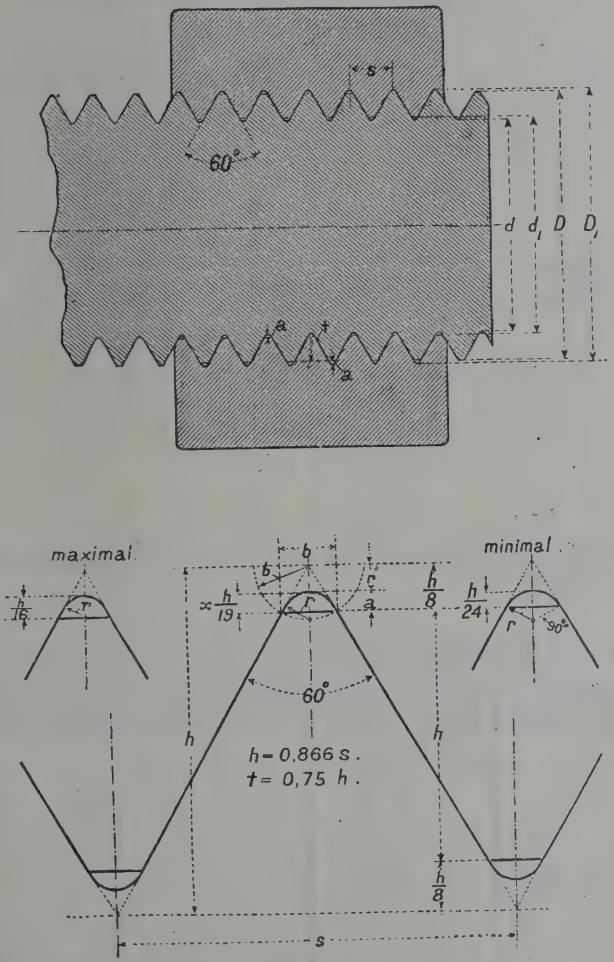

FIG. 8.

Wood Screws.

(Sometimes termed 'Screw Nails.')

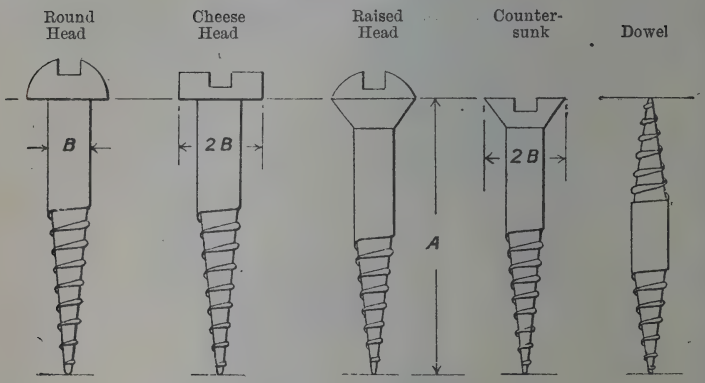

FIG. 9.

Wood screws are measured, as regards length (A), from the point to the portion normally flush with the surface of the material into which they are driven. Dowel screws are measured from point to point.

The number (size or thickness) (B) refers to the diameter of the shank or neck, and for screws of Nettlefold's manufacture is as follows :—

Number.	Diameter.	Number.	Diameter.	Number.	Diameter.	Number.	Diameter.
	In.		In.		In.		In.
1	·066	9	·178	17	·290	25	·402
2	·080	10	·192	18	·304	26	·416
3	·094	11	·206	19	·318	27	·430
4	·108	12	·220	20	·332	28	·444
5	·122	13	·234	21	·346	29	·458
6	·136	14	·248	22	·360	30	·472
7	·150	15	·262	23	·374	31	·486
8	·164	16	·276	24	·388	32	·500

Formula for ascertaining diameter of screw :—

(·014 × No.) + ·052 in. = diameter.

Example :—(·014 × 16) + ·052 in. = ·224 + ·052 = ·276 diameter of No. 16.

The diameter of the head may be taken as twice the thickness of the neck.

Numerous lengths are obtainable in each size from ¼ in. in the smaller sizes to 9 ins. in No. 32.

Larger sizes are made to order but not gauged, and most sizes are obtainable in iron or brass

NOTE ON WOOD SCREWS.

Wood screws may be put into the hardest of wood by the following process: A screw of the same size to be used is ground down to the form of a half-round bit. A hole, equal in diameter to the size of the screw at the bottom of the thread, is drilled into the wood, and the half-round tap is screwed in. This cuts a good thread, into which the screw may easily be screwed. Before introducing the screw, give it a good greasing with tallow, so that no binding can take place.

Screw Heads.

British Standard Heads for Small Screws.*

(No. 57—1920.) (*Abstract.*)

For all classes of head the diameter to be 1·75 times the full diameter of the thread.

The width of saw-cuts to be according to the formula,

$$S = \cdot 2\ D + \cdot 1m,$$

where

S = width of saw-cut, and D = full diameter of the thread in millimetres.

The standard depth of saw-cut to equal one-half the total depth of the head in all cases, such depth being measured at the centre of the head.

NOTES ON TABLE.

Columns 1 and 2 of the table give the nominal bore of the tube and the full diameter of the screw in the coupler for use with that tube. The diameter of this screw has been chosen, in all cases, so that the coupler can be screwed by hand on to the tube, leaving from four to eight threads exposed.

The Association have preserved the Old Whitworth Standards as far as possible in the simplified dimensions for screwing sizes on tubes up to 2¼ ins. nominal bore. The Association have been guided in fixing the gauge diameters of the larger screwing sizes by the advantages of making the outside diameters of the tubes even quarters of inches.

* By permission of the British Engineering Standards Association.

Bolts and Nuts.

According to the Whitworth system of standard sizes of bolts and nuts, the thickness of the bolt-head is seven-eighths of the diameter, and the nut is equal to the diameter.

In the Sellers' (American) system the heads and nuts are hexagonal, the thickness of the heads and of the nuts being equal to 1 diameter minus one-sixteenth inch. The breadth across the flats is equal to $1\frac{1}{2}$ diameters plus one-sixteenth inch.

† The figures in this column represent the maximum width across the corners correct to two decimal places. The figures in italics are those for *black* nuts

A chamfer of 30° from the face should be adopted on all bright nuts and bolt-heads. The interior diameter of the chamfer circle should not be appreciably less than the width across the flats.

TO LOCK A NUT.

(1).

In the absence of any of the regular nut-locking devices the work can still be done with an ordinary nut and washer. The stud or bolt used is first filed flat on one side at A, fig. 14, to

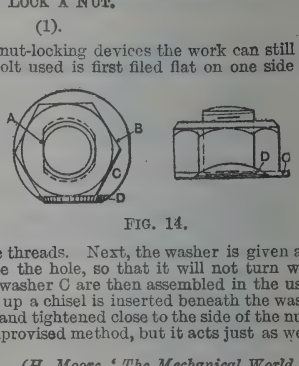

FIG. 14.

the depth of the threads. Next, the washer is given a few taps on one edge to elongate the hole, so that it will not turn when on the bolt. The nut B and washer C are then assembled in the usual manner, and when tightened up a chisel is inserted beneath the washer and the edge turned up at D, and tightened close to the side of the nut by hammering.

This is an improvised method, but it acts just as well as the regular locking devices.

(*H. Moore, 'The Mechanical World,' June* 22, 1923.)

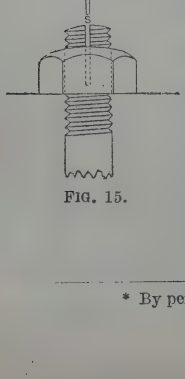

FIG. 15.

(2).

A slot S (fig. 15) is cut in the bolt with a hack-saw, and when the nut is tightly screwed home a cold chisel wedge C, whose width is less than the diameter of the bolt, is driven into the slot S (and then withdrawn) so as to spread out the end of the bolt, thus preventing the nut from unscrewing.

A serrated steel wedge can be driven into the slot if the nut is not required to be unscrewed again. (*H. R. Kempe.*)

* By permission of the British Engineering Standards Association.

Keys and Keyways.

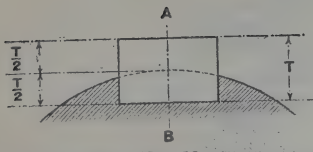

FIG. 18.

BRITISH STANDARD KEYS, KEY BARS, AND KEYWAYS.*

(No. 46—1909.) (*Abstract.*)

The keyway shall be cut in the shaft to a depth equal to one-half the thickness of the standard key it is intended to receive, and this depth shall be measured at the centre line (A–B) of the keyway.

For steam pipes allow 2½ inches per 100 feet for expansion.

British Standard Pipe Flanges.*

(No. 10—Part 2—1926.) (*Abstract.*)

Table D.—For Working Steam Pressures up to 50 lbs. per sq. in.

Nominal Pipe Size.	Diameter of Flange.	Diameter of Bolt Circle.	Number of Bolts.	Diameter of Bolts.	Thickness of Flanges.		
					Cast Iron	Cast Steel and Bronze.	Stamped or Forged Iron or Steel.
Ins.	Ins.	Ins.		Ins.	Ins.	Ins.	Ins.
¼	3¾	2⅝	4	½	½	⅜	3/16
⅜	4	2⅞	4	½	½	⅜	7/16
1	4¼	3¼	4	½	½	⅜	5/16
1¼	4¾	3 7/16	4	½	⅝	½	¼
1½	5¼	3⅞	4	½	⅝	½	¼
2	6	4½	4	⅝	¾	9/16	5/16
2½	6½	5	4	⅝	¾	9/16	5/16
3	7¼	5¾	4	⅝	¾	9/16	⅜
3½	8	6½	4	⅝	¾	9/16	⅜
4	8½	7	4	⅝	⅞	11/16	⅜
5	10	8½	8	⅝	⅞	11/16	½
6	11	9½	8	⅝	⅞	11/16	½
7	12	10½	8	⅝	1	¾	½
8	13¼	11½	8	⅝	1	⅞	½
9	14½	12¾	8	⅝	1	⅞	⅝
10	16	14	8	¾	1	⅞	⅝
12	18	16	12	¾	1⅛	⅞	⅝
14	20¾	18½	12	⅞	1⅛	1	¾
15	21¾	19½	12	⅞	1⅛	1	¾
16	22¾	20½	12	⅞	1⅛	1	¾
18	25⅛	23	12	⅞	1⅜	1⅛	⅞
20	27½	25¼	16	⅞	1⅜	1¼	1
21	29	26½	16	⅞	1⅜	1¼	1
24	32½	29½	16	1	1⅜	1⅜	1⅛

Bolt holes.—For ½-in. and ⅝-in. bolts the diameters of the holes to be 1/16-in. larger than the diameter of the bolts, and for larger sizes of bolts ⅛-in. Bolt holes to be drilled off centre lines.

* By permission of the British Engineering Standards Association.

Tables E. F, H, and J relate to pressures up to 100 lbs., 150 lbs., 250 lbs., and 350 lbs., respectively.

TABLE K.—For Working Steam Pressures up to 450 lbs. per sq. in.

Nominal Pipe Size.	Actual Outside Diameter of Wrought Pipe.	Diameter of Flange.	Diameter of Bolt Circle.	Number of Bolts.	Diameter of Bolts.	Thickness of Flange. Cast Steel and Bronze; Stamped or Forged Steel.
ins.	ins.	ins.	ins.		ins.	ins.
¼	13/32	4½	3¼	4	⅝	¾
⅜	1 7/16	4½	3¼	4	⅝	¾
½	1 11/16	5	3½	4	⅝	⅞
1	1 15/16	5½	3⅞	4	⅝	⅞

TAPPING.

It is a common occurrence for a tap to break when tapping hard metal. If the tap is ground away on the point, so that the first five or six threads are gradually bevelled, the risk of breakage may be largely avoided. The effect of grinding the end of the tap is to break up the chips into smaller pieces, and thus prevent clogging the threads of the tap. This will be found to be especially advantageous in tapping very hard rolled steel.

An easy rule for approximating tap-drill sizes is to deduct 1½ times the pitch from the outside diameter of the tap. In the case of a ⅜-in. tap, 16-pitch thread, for instance, 1½ times 1/16 = 3/32, and ⅜ − 3/32 = 9/32 = the diameter of the drill required for a ⅜-in. tap.

CORRECT TAP GRINDING.

Grinding a tap consists usually of grinding the taper at the end of the tap, and the clearance back of the cutting edge thus formed. This taper may be long, as in nut taps; short, as in plug taps; or almost none, as in bottoming taps. The principle remains the same in each case. What is required is that each flute shall have exactly the same taper, just enough clearance so that it will cut freely, and not enough to needlessly weaken the cutting edge.

Prior to the advent of tap-grinding machinery nearly all taps were ground by hand, with a resultant lack of uniformity in taper and clearance. Fig. 29 shows a section of a four-flute tap with each flute ground differently in the matter of clearance or backing off. The flute A, at the left, is ground with a straight-line clearance just sufficient to have the heel of the flute actually clear and not drag. This calls for an angle of 15°, as indicated, and results in a weak cutting edge, but the strongest possible with a straight-line clearance at the heel.

The flute B, at the top, shows a 15° convex clearance. A glance shows this to be excessive. Flute C, at the right, shows a straight-line clearance of 5°, and nearly half of the flute at the back is not cleared at all, leaving the tap to ride on that portion and keep the front of the flute from cutting. Flute D, at the bottom, shows a perfect grind for ordinary work. It is a 5° convex

clearance, and shows that with this small but sufficient clearance angle at the cutting edge, the back is perfectly cleared.

In addition to the correct clearance of taps, a uniform angle of taper for all flutes is necessary. The results of different tapers obtained by hand-grinding are indicated in fig. 27. Even a slight variation from the uniform taper angle means power wasted and taps broken. As the blunt angle flute strikes the side of a drilled hole, it throws the cutting end of the tap off centre and imparts to it a wabbling motion. This means a tapped hole that is oversized, allowing the screw to fit loosely. Tap A is correctly ground and will tap a hole true to size, properly located and

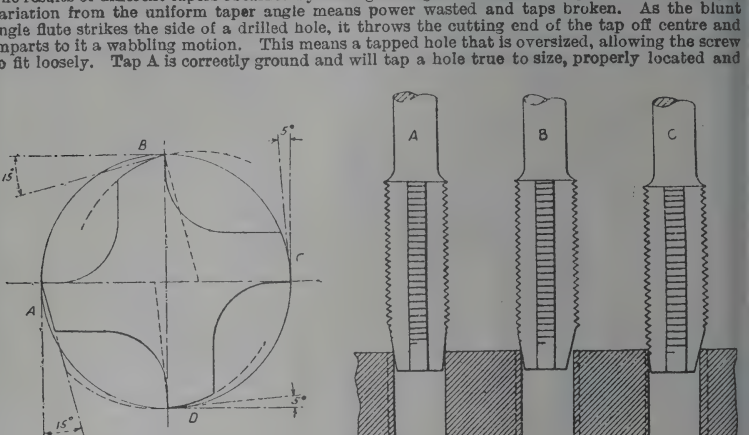

FIG. 29.

with smooth, accurately shaped threads. Tap B is ground with one flute at a more blunt angle than the other. This blunt flute is shown just as it strikes the drilled hole. Tap C shows a similar tap after it has been crowded over. The condition developed is readily seen.

(*' Railway Mechanical Engineer.'*)

THE "GUN" TAP.

A method of grinding a tap to give a cutting action similar to that of a turning tool is shown in fig. 30, which shows a ' Gun ' tap made by the Greenfield Tap & Die Corporation of America. The makers claim that the slope B of the face of the leading cutting edges (which are slightly hook-shaped, the edge being ground to give a negative rake) at A curls and projects the chips forward in an axial direction in front of the tap as tapping proceeds, the form of the chips, in steel, being spiral and more or less continuous. In this way the vicinity of the cutting operation at each flute is

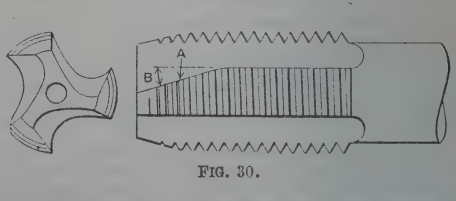

FIG. 30.

kept clear of swarf and the tap cuts freely, even through a long hole. The tap does not have to be backed out of long holes to clear a collection of chips from the flutes.

It is stated that the cutting pressure necessary with the ' Gun ' tap is 50 to 60 per cent. less than with an ordinary tap for the same size of thread. In deep holes the ' Gun ' tap has cut a full thread over four diameters long at a cutting pressure of 300 lbs., whereas an ordinary tap pulled up after tapping a full thread for a length of two diameters, the load being then 1,100 lbs., and stalling the machine.

Pipe Thread Tap Heads.

The Sheffield Small Tool Manufacturers have adopted the following list of sizes for the squares of pipe thread taps:—

No. of □.	Size of □ Inches. Fraction.	Size of □ Inches. Decimal.	Whitworth Thread Taps. Inches.	International Thread Taps. Millimetres.	Gas Tap. Inches.
0	7/64	·109	1/8	3 to 3½	—
1	9/64	·140	5/32	4 to 4½	—
2	5/32	·156	3/16	5	—
3	13/64	·203	¼	6 to 7	—
4	15/64	·234	5/16 and 3/8	8 to 10	⅛
5	9/32	·281	7/16	11 to 12	—
6	5/16	·312	½ and 9/16	13 to 14	¼
7	25/64	·390	5/8 and 11/16	15 to 17	3/8
8	29/64	·453	¾ and 13/16	18 to 21	½
9	35/64	·546	7/8 and 15/16	22 to 23	—
10	41/64	·640	1	24 to 26	⅝ and ¾
11	23/32	·718	1⅛	27 to 30	—
12	13/16	·812	1¼	31 to 33	⅞ and 1
13	27/32	·843	1⅜	34 to 36	—
14	29/32	·906	1½	37 to 41	1¼
15	1 5/64	1·078	1⅝ and 1¾	42 to 46	1½ and 1¾
16	1 13/64	1·203	1⅞ and 2	47 to 52	—
17	1 3/8	1·375	2⅛ and 2¼	54 to 58	2 and 2¼
18	1 7/16	1·500	2⅜ and 2½	60 to 64	—
19	1 29/64	1·625	2⅝ and 2¾	66 to 70	—
20	1 3/4	1·750	2⅞ and 3	72 to 76	2½ to 3

Intermediate diameters have same squares as sizes below.

The heads of fluted hand reamers have same size squares as Whitworth taps and International thread taps, respectively.

The sizes of squares are stated in fractions and in decimals of inches, to facilitate measurement with either the mechanics' rule or the micrometer calliper.

No. of □ may be quoted when ordering tap wrenches.

Work-tables of Machine Tools.

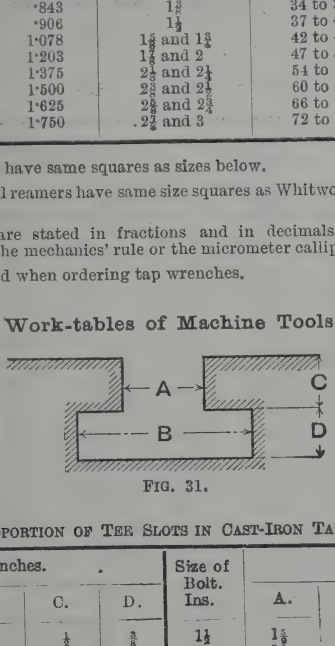

Fig. 31.

Keeping Bolts in Place in Open-slotted Tables.

When bolts have to be used for repeat work in drilling machine or other open-slot types of tables, the flopping about and dropping of these bolts becomes a time-wasting nuisance. Fig. 32 shows two methods of holding them firmly in position, so that work can be removed

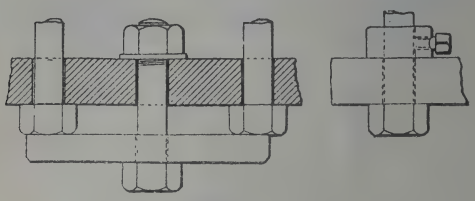

Fig. 32.

and a fresh piece substituted with the minimum of inconvenience. In the one case a clamp is suspended from a bolt and drawn up against the heads; in the other a loose collar is slipped down the bolt and tightened with a set-screw, an easier way than troubling to thread the bolt right down and putting a nut on. (*'Machinery.'*)

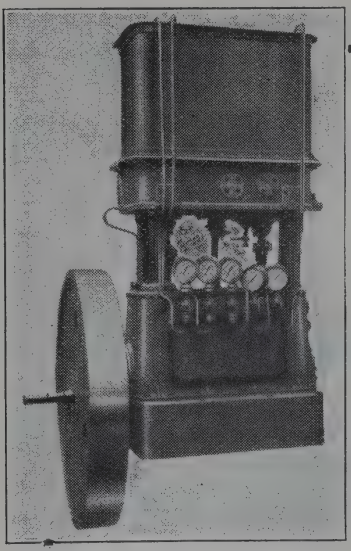
SECTION XXIII

THE ATMOSPHERE — WIND — AIR RESISTANCE — WIND-MILLS—TRANSMISSION OF POWER BY COMPRESSED AIR—AIR COMPRESSORS—PNEUMATIC DESPATCH TUBES

(With Contributions by Edward Butler, M.I.Mech.E., R. A. Sturgeon, A.M.I.C.E., and R. Myles Hook.)



BROTHERHOOD COMPRESSORS

for
Air
Oxygen
CO_2
Hydrogen
Ammonia
&c.

The illustration shows a five-stage compressor designed for a working pressure of $2\frac{3}{4}$ tons per square inch.

This is one example of the unrivalled range of Brotherhood Compressors.

(*See Editorial pages* 1254-1257.)

SECTION XXIII

THE ATMOSPHERE—WIND—AIR-RESISTANCE—WINDMILLS—AIR COMPRESSION—AIR COMPRESSORS—PNEUMATIC DESPATCH TUBES.

The Atmosphere.

Air consists, by volume, of oxygen 20·84 parts, of nitrogen, 79·16 parts; and by weight, of oxygen 23·15 parts, and of nitrogen 76·85 parts. Also 0·03 to 0·04 per cent., by volume, of carbonic acid.*

One cubic foot of ordinary dry air at normal pressure, temp. 62° F., weighs 532·5 grains (saturated 529 grains); or 1 lb. of air contains 13·146 cubic feet.

Dry air is 819 times lighter than water. Aqueous vapour, 1·4 per cent. by volume.

At 60° a cubic foot of saturated air contains 0·00083 lb. of moisture. This increases to 0·00285 lb. at 100° and 0·030 lb. at 200°. These are exactly the same as the weight of a cubic foot of saturated steam at the given temperatures.

The viscosity of air in C.G.S. units is 1·48 at 15° C. (59° F.) and 1·49 at 16·5° C. (61·7° F.).

The mean weight of a column of air 1 inch square and 45 miles high is 15 lbs.

Density of air $= \left(\frac{1}{4}\right)^{\frac{h}{6\cdot8}} = (0\cdot8156)$; Pressure of air, $p = 14\cdot7\,(0\cdot8156)^{h}$ lbs. per sq. in.

$$h = \frac{\log.\frac{p}{14\cdot7}}{-0\cdot0885228}$$

where h = height in miles above surface of earth.

At 6·8 miles above the surface of the earth the air is 4 times lighter than at the earth's surface; at 13·6 miles, 16 times; at 20·4 miles, 64 times. Total weight of atmosphere, 5,300 billion tons.

According to a writer in *Nature*, the result of experiments made with forty balloons (sent up in Great Britain) has been that the isothermal layer was reached more than thirty times. Its average height was 35,000 ft. (10·7 kiloms.); it is rather higher with a high barometer. The mean temperature found was − 53·6° F. (−77° C.), considerably higher than the Continental mean. The extremes observed in England were −22° F., near Ditcham Park, Hants, on July 24, and −78° F., near Oxford, on September 12, 1907. On the same day, November 11, 1907, the temperature was −42° F. at Ditcham at 36,000 ft. altitude, −58° F. in Oxfordshire at 38,500 ft., and −74° F. near Manchester at 37,000 ft. The existence of an isothermal layer in equilibrium in which the fall of temperature suddenly stops, and yet in which such great differences of temperature occur at spots not very far from one another, is difficult to understand, especially considering the low atmospheric pressure at these heights. (See also page 216.)

To consume 1 lb. of coal requires 11½ lbs., or 150 cubic feet, of air to combine with it.

The work stored up in 1 cu. ft. of air at atmospheric pressure, i.e. the work it would do if allowed to expand into an absolute vacuum = 5,188 ft. lbs.

The expansion of air, like all other elastic fluids, is uniform at all temperatures.

---

* Air contains 15 parts of 'neon' and 5 parts of 'helium,' in one million volumes (*Dewar*).

If h = height of barometrical column of mercury ; K = number of square inches in section of tube ; 13,568 ozs., or 848 lbs. = weight of cubic foot of mercury at mean temperature : p = number of pounds pressure of air on square inch of surface ; then

Pressure of atmosphere on K sq. ins. $= p \times K$. Weight of column of mercury $= \frac{Kh}{1728} \times 848$.

But column of mercury balances the pressure of the atmosphere ; therefore

$$p \times K = \frac{Kh}{1728} \times 848, \quad \text{or,} \quad p = \frac{848}{1728} \times h = \frac{53h}{108} = \frac{h}{2} \text{ very nearly.}$$

Hence it appears that *the pressure of the atmosphere in pounds per square inch is very nearly equal to half the column of mercury in the barometer-tube in inches.*

The column of mercury in the barometer in this country varies from 28 to 31 ins. ; therefore the mean column is 29·5 ins. ; and by the foregoing result the mean pressure of the atmosphere will be about 14·7 lbs. per square inch.

Rankine assumes a standard English atmosphere to be 14·704 lbs. per square inch in the latitude of London, or equal to a mercury column 29·922 ins. high at 32° F., which = 30 ins. at 57·8° F.

The metrical atmosphere, 760 mm. (29·922 ins.), at 0° C. (32° F.) = 1·0333 kilograms per square cm., or 14·6967 lbs. per square inch, at Paris = 14·686 lbs. at New York.

To find the barometric height, H, at any latitude, l,

$$H = 760 \times \frac{(1 + 0{\cdot}00531 \sin^2 48° 50')}{(1 + 0{\cdot}00531 \sin^2 l)} \text{ mm.},$$

where 48° 50′ is the latitude of Paris.

The altitude or head of the atmosphere at uniform density will be that of a column of water 33·95 ft. high divided by the specific gravity of air (·0012046), or 28,183 ft. The velocity due at the foot of this head will be : $V = 8{\cdot}02 \sqrt{28183} = 1346{\cdot}4$ ft. per second, the velocity at which the air will pass into a vacuum. The motions and effects of gases by the force of gravity are precisely the same as those of liquids. Under like conditions a conduit will discharge 30·55 times more air than water.

Liquid Air.

Liquid air is produced by passing highly compressed air through a counter flow heat exchanger followed by an expansion device. On expansion the air is cooled and the cold air thus produced passes back through the heat exchanger, so cooling the incoming compressed air. The cooling is thus self-intensive, and finally results in liquefaction of part of the expanded air. The unliquefied part escapes through the heat exchanger, and so keeps up the cooling effect. The expansion may take place through a nozzle, or in an expansion engine with the output of external work. The initial pressure used varies in different systems from about 45 atms. to 200 atms. About 8 to 12 per cent. of the air supply is liquefied, and the power required is from 1 to 2 h.p. hrs. per lb. of liquid produced, according to size and type of plant employed.

The critical temperature of air, above which it cannot be liquefied, is −140° C., and the corresponding critical pressure is 39 atms. The boiling point at atmospheric pressure is about −190° C., and the latent heat of evaporation about 50 calories. The specific gravity of the liquid is about 0·88.

If liquid air (21 per cent. O_2) is allowed to evaporate quietly it gives off a vapour containing about 7 per cent. O_2 owing to the fact that nitrogen boils at a temperature 12° C. lower than that of oxygen. The remaining liquid consequently becomes richer in oxygen as evaporation proceeds, and the boiling point rises until finally a temperature of −184° C. is reached (the boiling point of liquid oxygen).

The chief use of liquid air is in the process of obtaining oxygen and nitrogen from the atmosphere by means of liquefaction and distillation. Argon and neon are also obtained in the same way by additions to the ordinary oxygen or nitrogen apparatus.

Liquid air as such is used industrially for obtaining very low temperatures. One application is the freezing of mercury vapour during the evacuation of radio valves where the evacuation is performed by mercury vapour pumps. The mercury vapour is prevented from reaching the valves by the insertion of a liquid air trap in the pump circuit. A somewhat kindred use is the charcoal pump, in which specially prepared charcoal is cooled in liquid air. When so cooled the charcoal absorbs a large volume of air, and so can produce a higher vacuum than is obtainable by any other known method.

Liquid oxygen is used in breathing apparatus either for mine rescue work or for high altitude flying. It is also used in conjunction with special cartridges as an explosive for use in quarries

and mines. The chief advantages of this explosive lie in the facts (1) that it can generally be manufactured on the spot, as suitable material for the cartridges can be obtained almost anywhere, and (2) that neither the cartridge nor the liquid oxygen is in itself explosive. The actual soaking of the cartridge which renders it explosive is only performed immediately before nsertion into the bore hole.

See also Section XXXIII, Part I.

Velocity of Air.

When air passes into an air of less density, the velocity of its passage is measured by the difference of the densities of the two.

H and h = densities of the air in inches of mercury; t = temperature (F.°) at the time of passage; and V = velocity of air in feet per second.

$$V = 1347{\cdot}4\sqrt{\frac{H-h}{h}\left(1+0{\cdot}002088t\right)}.$$

Pressure against a Plane Surface moved through the Air.

P = pressure against plane. a = area of plane, in square feet. v = velocity, in feet per second
v_1 = velocity in miles per hour.

$P = {\cdot}00142av^2$ lbs.* $\quad P = {\cdot}0029av_1^2$ lbs.*

$P = ({\cdot}003 + {\cdot}00004q)\,av_1^2$ lbs.,† where q = ratio of sides of rectangular plate.

The quantity ·003 decreases as v_1 increases, being ·0029 for 90 miles, and ·0032 for 0 to 25 miles.

Horse-power required to move a Plane Surface against the Air.

H.P. = horse-power. a = area of plane, in square feet. v = velocity, in feet per minute.

$H.P. = {\cdot}000{,}000{,}000{,}010{,}6av^3$.

TABLE SHOWING HORSE-POWER CONSUMED IN MOVING A PLANE SURFACE AGAINST THE AIR.

Speed in		H.P. per Sq.Ft. of Effective Surface.	Speed in		H.P. per Sq. Ft. of Effective Surface.
Miles per Hour.	Feet per Min.		Miles per Hour.	Feet per Min.	
10	880	0·00722	50	4,400	0·903
15	1,320	0·0244	75	6,600	3·05
20	1,760	0·0514	100	8,800	7·23
25	2,200	0·110	150	13,200	24·4
30	2,640	0·195	200	17,600	57·8

As a result of tests, M. Eiffel found that, for velocities of from 60 ft. to 130 ft. per second, the resistance offered by air to a moving surface is practically proportional to the square of the velocity, although the exponent increases slightly and gradually when velocities exceeding 100 ft. per second are employed. The resistance or pressure in pounds, P, is represented by the product KSV^2, where K is a constant depending on the size and shape of the surface tested; S is the area of the surface in square feet, and V is the velocity in miles per hour. At ordinary temperatures and a barometric pressure of 760 mm., M. Eiffel found that the value of the coefficient K ranged from 0·00286 to 0·00327, the latter value being apparently a maximum attained only with large surfaces. Thus, for a circular surface of 1 sq. ft., the value of K was 0·00286, for a square surface of the same area 0·00295, and for an area of 10 sq. ft. 0·00323. He also found that the resistance of an inclined surface is practically the same as that of a normal one, when the perpendicular to the surface makes an angle less than 30° with the direction of motion. For greater angles the resistance proportionately decreases (zero at 90°). On pressure boards ranging from 25 sq. ft. to 100 sq. ft. in area, which were mounted at the top of a 50 ft. tower, Dr. T. E. Stanton found, from a large number of experiments, that the mean value of this constant was 0·0032.

Dr. Hutton deduced that the resistance of air varied as the square of the velocity nearly, and to an inclined surface as the 1·84 power of the sine × cosine.

The figure of a plane makes no appreciable difference in the resistance, but the convex surface of a hemisphere, with a surface double the base, has only half the resistance.

At high velocities the resistance becomes nearly a constant quantity.

The resistance of the air to a train of cars in a dead calm was found to be $\frac{1}{356}$ of their weight.

The velocity of a train of cars which gave a resistance of $\frac{1}{256}$ of the load with a fair wind was 34½ miles per hour, and only 27¾ with an adverse wind.

* T. E. Stanton, National Physical Laboratory. † Hagen

Flow of Air.

Weight of Air Passing Through a Nozzle.

The weight of air at atmospheric pressure passing through a properly-designed nozzle into any vacuum of not less than 8 lbs. may be calculated as follows (Leblanc) :—

W = lb. weight per hour ; A = area of nozzle neck in square inches ; T = atmospheric temperature in deg. Cent.

$$W = \frac{20330A}{\sqrt{T + 273}}$$

Air Friction.

Recent experiments on the flow of air through smooth sheet steel ducts varying in size from 12 ins. to 48 ins. in diameter, at velocities ranging from 1,000 ft. to 2,400 ft. per min., appear to show that the average value of the coefficient of friction is 0·0035.

Impulse of Wind.

V = velocity of wind. D = direct impulse in pounds on one square foot.

$D = V^2 \times \cdot00271$, where V is in miles per hour } *
$D = V^2 \times \cdot00312$, where V is in knots per hour }

Model experiments carried out in a wind tunnel at Washington show that a wind blowing at 76 miles per hour produces a pressure of 22 lb. per sq. ft. on a tall building.

Wind Velocity by Robinson Anemometer.

If v = velocity of anemometer cups in miles per hour ; V = velocity of wind in miles per hour; then,

$$V = 2v + 4.$$

Instrument fails to record velocities below 4 miles per hour.

(*W. H. Dines*, 'Report of Astronomer Royal, 1921.'

* Recent researches have shown that the constants ·00271 and ·00312 are apparently too small by about 6 per cent.

WINDMILLS.

(Contributed by Edward Butler, M.I.Mech.E.)

The driving shaft of a windmill situated on level ground should, with a tower of moderate height, be tilted *upwards* at an angle of 6° to 8°. If on a low hill with the fall against the prevailing wind the shaft is better horizontal, but when situated on a steep hill the best result will be obtained by tilting the shaft *downwards* a few degrees.

The shaft should be mounted so that the driving-wheel faces the wind in either direction, and at a height ranging from 20-25 ft. on high ground, and 50-70 ft. on low ground, and so that it is clear of buildings or trees.

The tower should, in ordinary circumstances, be of sufficient strength to hold up against a 40-mile storm with a wind pressure of 8 lbs. per sq. ft. On exposed elevations subject to wind velocities exceeding this, a windmill unless specially constructed is not suitable.

WIND ACTION.

Velocity per hour in miles.	Pressure per sq. ft. in lbs.	Description of Wind.	Action on Windmill.
5	0·125	Faint breeze . .	Will not drive.
8	0·33	Breeze . . .	Will start against light load.
10	0·5	Fresh breeze . .	Will run slowly.
15	1·125	Good wind . .	Will run steadily.
20	2·	Strong wind . .	Gives best service.
25	3·125	Very strong wind .	Maximum useful effect.
30	4·5	Gale	Should be partly furled or held out of the wind.
40	8·	Storm	Must be totally put out of action.
60	18·	Violent storm .	Not safe.

100	50·	Tornado . . .	" "

Power of Windwheels.

The total momentum of wind is,

$$\frac{0{\cdot}08}{32{\cdot}2} \times \text{area} \times \text{velocity}^2 = 0{\cdot}0025\ AV^2, \text{ approximately.}$$

The turning moment at starting, for each vane, equals

$$0{\cdot}002\ AV^2 \cos\theta r,$$

and when in motion is

$$0{\cdot}0015\ AV^2 \cos\theta r \text{ for moderate speed,}$$

the constant ·0015 decreasing to 0·0012 with increase of speed:

where A = area of vane; V = velocity of wind; θ = angle to the axis of rotation; r = mean radius; 0·08 is the mean weight of one cubic foot of air. Velocity in ft. per sec. is to miles per hour as 22 is to 15.

HORSE-POWER OF WINDWHEELS.

Shaft or b.h.p. of a 4-armed wheel with cloth sails

$$= \frac{v^2 r^2}{512477}\ (\textit{Rankine}), \quad \frac{4\ A v^3}{1145833}\ (\textit{Weisbach}).$$

The brake h.p. of a multi-vaned wheel

$$= \frac{0{\cdot}6 \times 0{\cdot}78\ (D^2 - d^2) \times V^2}{33000};$$

where,

A = area of one vane; D = total diameter of wheel; d = clearance diameter at centre; = radius of sail tips; V = velocity in feet per second.

A windwheel (Dutch pattern) with four cloth sails, each 24 ft. in length and 6 ft. in breadth, will develop 4·5 b.h.p. in a 20-mile wind.

Windwheels with multiple vanes have a considerable advantage in starting with low velocity winds and in slow running.

The power of a windwheel is not so great as is popularly supposed. A 16 ft. wheel, for instance, with multiple cambered steel vanes, only develops about 1 b.h.p. in a 15-mile wind, and this is reduced to less than one-half in a 10-mile wind, although increased to nearly double in a 20-mile wind.

Construction.

According to windmill practice (old type) the wheel may have 4, 5, or 6 cloth sails of rectangular form, the length being equal to five times the breadth; but the total surface should not exceed one-third of the whole surface described by the radial arms carrying the sails. The angles of the cross bars for supporting the sails, which commence at one-seventh from the wheel centre, are usually 24°, 21°, 18°, 9°, 3°, from the plane of motion.

While more power can be gained by increasing the sail surface to more than one-half the wheel area, the difficulty is such with the old practice of using cloth sails that the sail area seldom exceeds one-third and is more often reduced to one-fourth.

The angles of the sails to the plane of motion, according to Smeaton, should be 20°, 19°, 18°, 16°, 12½°, 7°; and again, to Forrester, as 24°, 21°, 18°, 14°, 9°, 3°.

In multi-vane windwheels, the vanes—either oil-soaked wood slats, or cambered steel plates of light construction and galvanised—are carried by a series of 6-8 steel or wooden arms, fixed to a steel boss. The arms are braced to an extension of the wheel boss by tension rods. The vanes are fastened to two sets of cross-bars, connecting the arms together, in sections of 8 to 15, according to wheel diameter and angle to the plane of motion; this varies from 20° to 40°, but is generally 25° in flat or cambered vanes of uniform angle. The steeper the angle the narrower the vanes, to reduce whirl resistance. For direct connected pumps the angle is steeper than for geared down pumps. Steel vanes are cambered more for rigidity than for any increased driving efficiency. There is some advantage in forming the angle to suit the radius, but is not of such consequence as with wide cloth sails. What is of more importance is for the shaft to run in well lubricated roller bearings and for the turntable to move freely so that the wheel shall be held square to a light wind.

Power Control.

In windwheels with wide cloth sails, these are furled to suit either the load or the wind. In wheels with multiple vanes the usual practice is to fit a governor-vane on one side, at a right-angle to the wheel shaft, and for the tail-vane to be swivelled to the turntable, and to be held end-on either by a spring or a weight, or, better still, by a series of weights chained together. These weights should be proportioned for the governor-vane so as to pull the turntable, and the wheel with it, partly out of the wind as soon as the velocity increases 20-25 m.p.h., and to bring round the wheel edge-on to the wind in a storm.

Wind Pumps.

The popularity of wind-driven pumps is due to the introduction of the multiple-vaned wheel and to automatic governing, in combination with light easily-erected steel towers, the average power developed ranging from 1 to 6 shaft h.p., with a wind velocity of 15 m.p.h. (22 ft. per sec.), a 20-mile wind nearly doubling this power, and a 10-mile wind generating about half the power obtained by a 15-mile wind.

In ordinary practice the pumping capacity of a wind engine, as expressed in pounds of water raised per minute by pressure-head in feet, rarely exceeds from 25 to 35 per cent. of the wheel h.p., but is influenced by wheel diameter, the angle of the vanes, and the method of transmitting the power to the plunger.

In geared-down transmissions, the wheel-shaft pinion should be situated at the side of the pump wheel, and not above or below it. This disposition reduces friction and maintains correct alignment and mesh of the cogs.

Owing to the very inadequate fly-wheel effect of a windwheel, it works at considerable disadvantage in driving single-acting pumps direct, and only less so when geared down; double acting, or better, 3-throw single-acting pumps, oppose a more equable torque, but are impracticable for small installations. For this reason a rack or mangle transmission is peculiarly applicable to a wind-driven pump, as shown in the higher duty and efficiency in the table below.

The location of a wind pump is generally influenced more by the available water supply than from any consideration of available wind-power, the tower usually being constructed high enough—50 to 70 ft.—to clear all obstacles around for a distance of 300 to 400 ft. Under normal conditions eight hours' pumping only can generally be relied upon as a daily average; so that to make an installation successful a storage-tank or reservoir should be provided, the minimum capacity of which may with advantage equal from four to seven days' pumping, although a larger reserve is often allowed for.

AIR COMPRESSION.

RELATION BETWEEN PRESSURE AND VOLUME.

If

p = actual pressure of air in a container; p_1 = actual pressure of air when compressed;
P = gauge „ „ „ P_1 = gauge „ „ „
v = volume of air at pressure p; v_1 = volume of air when compressed;

then,

$$\frac{p}{p_1} = \frac{P + 14{\cdot}7}{P_1 + 14{\cdot}7} = \frac{v_1}{v},$$

the compressed air being *at the same temperature* as the air before compression—that is to say, if the heat due to the compression is allowed to become dissipated.

If the air is compressed from atmospheric pressure (i.e. if gauge pressure P = 0), then

$$\frac{14{\cdot}7}{P_1 + 14{\cdot}7} = \frac{v_1}{v},$$

or,

$$P_1 = 14{\cdot}7\frac{v - v_1}{v_1}, \quad \text{and} \quad v_1 = v\frac{14{\cdot}7}{P_1 + 14{\cdot}7}.$$

Example 1.—What gauge pressure (P_1) would be required to reduce 5 cub. ft. (v) of air at atmospheric pressure down to 3 cub. ft. (v_1), at the same temperature?

$$P_1 = 14{\cdot}7\frac{5 - 3}{3} = 9{\cdot}80 \text{ lbs.}$$

Example 2.—What volume (v_1) will 1 cub. ft. of air occupy when compressed to 30 lbs. gauge pressure (P_1), at the same temperature?

$$v_1 = 1\frac{14{\cdot}7}{30 + 14{\cdot}7} = 329 \text{ cub. ft.}$$

If the heat is not allowed to disappear when the air is compressed, then

$$\frac{14{\cdot}7}{P_1 + 14{\cdot}7} = \left(\frac{v_1}{v}\right)^{1{\cdot}408}$$

or,

$$P_1 = 14{\cdot}7\frac{v^{1{\cdot}408} - v_1^{1{\cdot}408}}{v_1^{1{\cdot}408}}, \quad \text{and} \quad v_1 = v\left(\frac{14{\cdot}7}{P_1 + 14{\cdot}7}\right)^{{\cdot}7102}.$$

If $P_1 = 30$, as in the case of *Example* 2, then the value of v_1 instead of being ·329, will be

$$(·329)^{{\cdot}7102} = ·454 \text{ cub. ft.}$$

WORK AND HORSE-POWER IN COMPRESSED AIR.

(1)

Work.

The effective work, W, stored up in 1 cu. ft. of compressed air (or the work required to compress the air) at a gauge pressure (pressure above atmosphere) of P_1 lbs. per sq. in. is

$$W = 352{\cdot}94\,(P_1 + 14{\cdot}7)\left(1 - \left(\frac{14{\cdot}7}{P_1 + 14{\cdot}7}\right)^{0{\cdot}29}\right) \text{ ft. lbs.}$$

Example.—1 cu. ft. of compressed air at a gauge pressure of 10 lbs. (the resulting heat not being allowed to disappear when the compression takes place) will contain:

$$352{\cdot}94 \times 24{\cdot}7\left(1 - \left(\frac{14{\cdot}7}{24{\cdot}7}\right)^{0{\cdot}29}\right) = 352{\cdot}94 \times 24{\cdot}7(1 - 0{\cdot}86028) = 1{,}218 \text{ ft. lbs. o}$$

effective work, *i.e.* the work it would do in expanding down to atmospheric pressure.

Horse-Power.

The H.P. required to produce 1 cu. ft. per min. of compressed air at P_1 lbs. pressure, i

$$W \div 33{,}000, \quad \text{or,} \quad H.P. = 0{\cdot}0107\,(P_1 + 14{\cdot}7)\left(1 - \left(\frac{14{\cdot}7}{P_1 + 14{\cdot}7}\right)^{0{\cdot}29}\right).$$

Example.—To produce 1,000 cu. ft. per min. of compressed air at 10 lbs. pressure woul require

$$H.P. = 1{,}218 \div 33{,}000 \times 1{,}000 = 36{\cdot}9.$$

(2)

Work.

The effective work, w, stored up in 1 cu. ft. of air at atmospheric pressure when compressed to a gauge pressure of P_2 lbs. per sq. in., is

$$w = 352{\cdot}94 \times 14{\cdot}7 \left(\left(\frac{P_2 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right) = 5188{\cdot}2 \left(\left(\frac{P_2 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right) \text{ ft. lbs.}$$

Example.—1 cu. ft. of atmospheric air, when compressed to a gauge pressure of 10 lbs. (the resulting heat not being allowed to disappear when the compression takes place), will contain

$$5188{\cdot}2 \left(\left(\frac{24{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right) = 5188{\cdot}2 \, (1{\cdot}1624 - 1) = 843 \text{ ft. lbs. of effective work.}$$

Horse-Power.

The H.P. required to compress 1 cu. ft. per min. of air at atmospheric pressure to P_1 lbs. gauge pressure, is

$$W \div 33{,}000, \text{ or, } \text{H.P.} = 0{\cdot}157 \left(\left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right).$$

Example.—To compress 1,000 cu. ft. per min. of atmospheric air to 10 lbs. gauge pressure would require

$$\text{H.P.} = 843 \div 33{,}000 \times 1{,}000 = 25{\cdot}6.$$

(3)

$$\frac{W}{w} = \left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}7102}.$$

Example.—If $P_1 = 10$ lbs.,

$$\frac{W}{w} = \left(\frac{24{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}7102} = 1{\cdot}446.$$

INCREASE OF TEMPERATURE OF AIR BY COMPRESSION.

If air at atmospheric pressure and at a temperature $t_1°$ F. be compressed suddenly to a gauge pressure P_1, then the temperature will be raised to $t_2°$ F., where

$$t_2° = (459 + t_1°) \left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 459.$$

Example.—If air at 32° F. temperature ($t_1°$) be compressed to 10 lbs. gauge pressure (P_1), then temperature $t_2°$ of air will be raised to

$$t_2° = 491 \left(\frac{24{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 459 = 491 \times 1{\cdot}162 - 459 = 112° \text{ F.}$$

PRESSURE OF AIR PRODUCED BY INCREASE OF TEMPERATURE.

If air at atmospheric pressure in a closed vessel and at $t_1°$ F. be raised to $t_2°$ F., then the gauge pressure, P_1, of the air will be

$$P_1 = 14{\cdot}7 \left(\frac{459 + t_2}{459 + t_1} \right)^{3{\cdot}45} - 14{\cdot}7.$$

Example.—If $t_1° = 32$, $t_2° = 112$, then $P_1 = 14{\cdot}7 \left(\frac{571}{491} \right)^{3{\cdot}45} - 14{\cdot}7 = 24{\cdot}7 - 14{\cdot}7 = 10$ lbs.

INCREASE OF VOLUME OF AIR BY INCREASE OF TEMPERATURE.

If a volume, V_1, of air at atmospheric pressure and at $t_1°$ F. be raised to $t_2°$ F., the air being allowed to expand freely, then the volume V_2 at $t_2°$ F. will be

$$V_2 = V_1 \frac{461 + t_2°}{461 + t_1°}.$$

Example.—If volume V_1 of air at 32° ($t_1°$) be 1,000, then volume V_2 at 525° ($t_2°$) will be:

$$V_2 = 1{,}000 \frac{461 + 525}{461 + 32} = 1{,}000 \times \frac{986}{493} = 2{,}000.$$

The following table gives the increase in volume from 32° F:—

INCREASE OF VOLUME OF AIR BY INCREASE OF TEMPERATURE FROM 32° F.

F.°	V.	F.°	V.	F.°	V.	F.°	V.	F.°	V.

AIR COMPRESSORS.

The mechanical efficiency of air compressors is about 60 per cent. at 5 pounds per square inch, increasing to 80 per cent. at 40 pounds per square inch and above. It is quite usual for the best makes to attain an efficiency exceeding 90 per cent., but for general purposes it is wiser to assume the lower figure. In the case of machines of small output and low pressure, the efficiency is frequently below 50 per cent.

In providing a driving unit for an air compressor, the type of machine should be considered before fixing the size of the driver. Thus, the turning effort required by a single-acting, single-cylinder air compressor may vary considerably above and below the mean, and allowance must be made for this, particularly in the case of direct-coupled drives.

DESIGN OF AIR COMPRESSORS.

The best practice adopted in the design of air compressors is as follows:—The maximum terminal pressures are, for one stage, 80 lbs. to 100 lbs. per sq. in.; two stages, 600 lbs. per sq. in.; three stages, 1,500 lbs. per sq. in.; four stages, 2,500 lbs. to 3,000 lbs. per sq. in.; five stages, 4,500 lbs. per sq. in.; and above 4,500 lbs. per sq. in., six or seven stages to 6,000 lbs. per sq. in., which is about the highest pressure for which an air compressor has been constructed. In the case of very small machines these pressures, for a given number of stages, are often exceeded in order to reduce complication. For example, machines have been constructed and work quite satisfactorily when compressing to 2,500 lbs. per sq. in. in two stages. The temperatures attained, however, make it necessary to carry out the cylinder lubrication by soapy water.

(*J. M. Ford, in a paper read before the Greenock Association of Shipbuilders and Engineers.*)

'BROTHERHOOD' AIR COMPRESSORS FOR MODERATE PRESSURES.

(*Peter Brotherhood, Ltd., Peterborough.*)

These compressors are made in a wide range of sizes, for small capacities of the single-acting trunk-piston type and for larger capacities of the double-acting type. The former are lubricated automatically, and the latter by forced lubrication.

BROTHERHOOD AIR COMPRESSOR

FIG. 1.—Details of Valves.

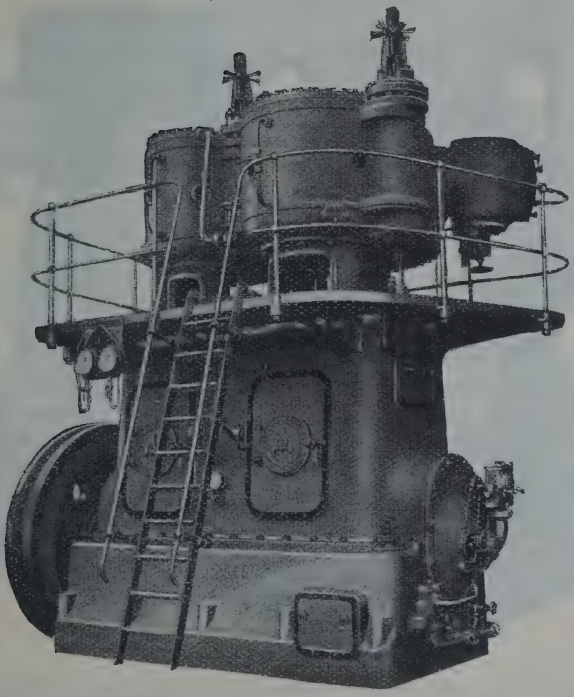

FIG. 2.

BROTHERHOOD AIR COMPRESSOR.

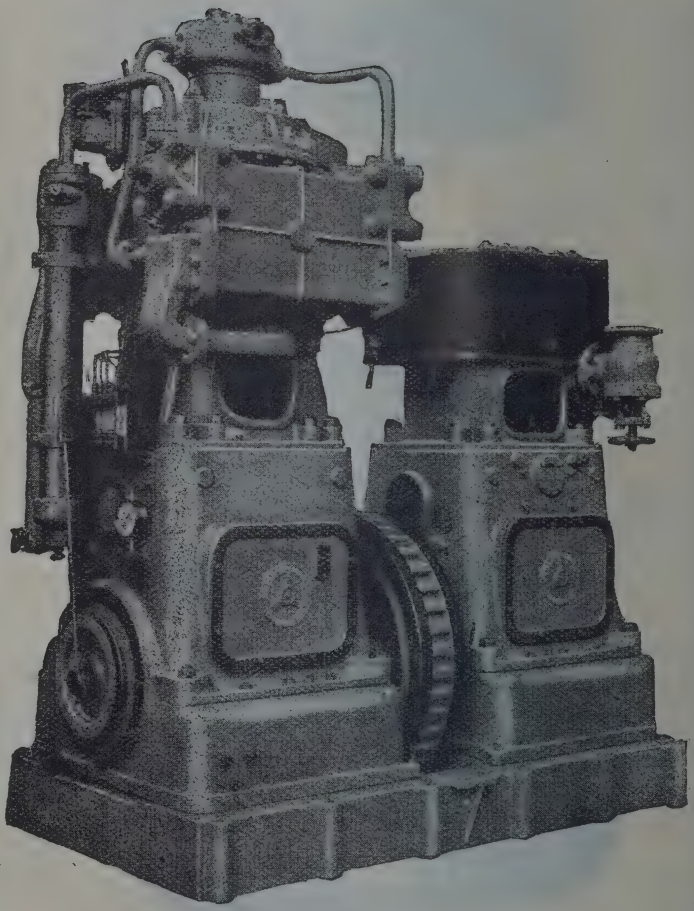

FIG. 3.

The single-acting types are designed for one or two stage, working up to a free air capacity of about 200 cu. ft. per minute, and are suitable for driving by belt, motor, or engine.

The double-acting types include single-line simple and tandem two-stage machines up to about 800 cu. ft. of free air per minute, and two-line simple and two-stage up to about 6,000 and 5,000 cu. ft., respectively.

The valves, which are illustrated on fig. 1, p. 1255, combine a large opening with very small moving mass, and will operate continuously at very high speeds.

The general construction of the double-acting types is shown on fig. 2, which illustrates a two-stage machine of 4,000 cu. ft. free air capacity.

The governing adopted varies according to the form of drive employed; for belt or motor drive the compressor is unloaded and reloaded as the air in the receiver rises or falls above and below the normal. For steam drive the speed is regulated and the air discharge controlled by a combined centrifugal and pressure governor.

'Brotherhood' High-Pressure Compressors for Air or Gas.

(Peter Brotherhood, Ltd., Peterborough.)

Brotherhood multi-stage compressors embody an exceptionally wide range of types resulting from development and research extending over sixty years. Standard types deal with pressures ranging from 600 to 6,000 lbs. per sq. in., in three to six stages of compression.

With the exception of compressors for oxygen, all piston and gland packings are of the metallic ring type, and except for special purposes, all classes have the working parts enclosed and lubricated under pressure.

Fig. 3 shows a three-stage air compressor for auxillary air service for fuel injection and manœuvring in a motor ship.

The capacity of the compressor is 300 cu. ft. of free air per minute compressed to 1,000 lbs. per sq. in. at 350 r.p.m. The compressor is driven by a Brotherhood Force Lubricated Steam Engine developing 140 b.h.p.

Westinghouse Air Compressors.

(Westinghouse Brake and Saxby Signal Co., Ltd., 82 York Rd., King's Cross, London, N. 1.)

The valve motion of the Westinghouse type of steam-driven air compressor is simple and compact, being entirely in the tophead, and all its parts are so arranged as to readily permit of examination or replacement. Should repairs to the valve mechanism be necessary, the tophead can be quickly removed and replaced by another, so that no unnecessary delay need occur through the compressor being put of service, pending repair. The air valves are contained in separate cases, so placed that they can readily be taken out.

The compressors are arranged vertically, and consist of a steam cylinder connected by a centre-piece to an air cylinder, or air cylinders, for either simple, compound, or three-stage compression. The three-stage compressor, figs. 4 and 5, is so constructed that air for compression is inhaled only on the upstroke of the piston, whilst on the downward stroke air at atmospheric pressure is drawn into and circulates around the inner walls of the cylinder and piston, to be again expelled on the succeeding upstroke; thus a supply of cool air is drawn into the interior of the compressor at every alternate stroke, and the compressor is air-cooled internally as well as externally; the result being that air compressed up to 300 lbs. per square inch is delivered at a temperature not exceeding 266° F., rendering the employment of water-cooled jackets unnecessary with this type of compressor.

For service on electric railways, the Westinghouse Brake & Saxby Signal Co., Ltd., manufacture air compressors driven direct by special slow-speed electric motors and also geared compressors driven by high-speed motors. Both of these types are equally suitable for industrial service.

Belliss High-Speed Forced-Lubricated Compressor.

(Belliss & Morcom Ltd., Birmingham.)

This type of compressor, fig. 6, p. 1255, embodies the best features of the Belliss engine, including the system of forced lubrication originated by the firm in 1890 (see Section XXX., Part III.). The working parts are generally the same as those for the 'C' type engine described in the section referred to. The air cylinders are water-jacketed and two-stage, as desirable for pressures in excess of 60 lbs. per sq. in., except in the case of quite small compressors.

WESTINGHOUSE THREE-STAGE AIR COMPRESSOR.

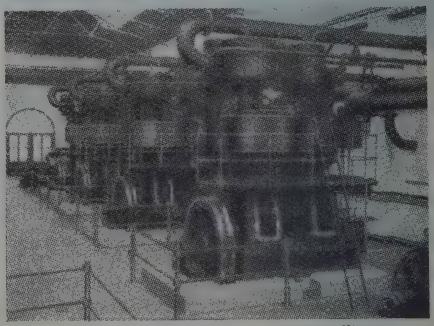
RECIPROCATING AND ROTARY TYPES



4 Steam-Driven Compressors at a Colliery.
Each 3000 cubic feet capacity.

BELLISS & MORCOM, LTD.

BIRMINGHAM.

ESTABLISHED 1852.

F. 1259

The compressor shown is adapted for being directly connected to an electric motor or for rope or belt driving. When operated at constant speed the air supply is controlled by an automatic valve on the inlet as shown, the valve being of the equilibrium double-beat type and con-

BELLISS AIR COMPRESSOR.

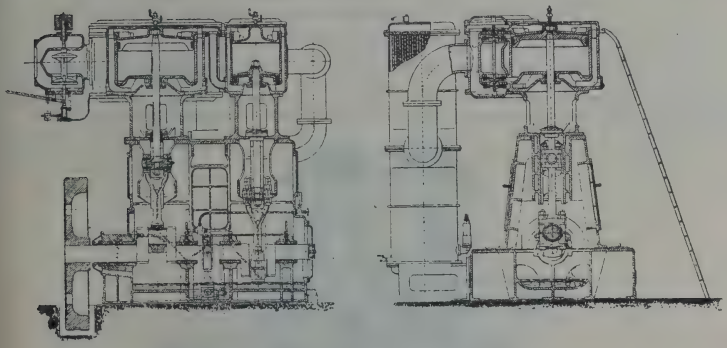


FIG. 6.—The Belliss Two-Stage Air Compressor.

trolled by an air relay, so designed that on the air pressure exceeding the intended pressure by 3 to 5 per cent. the air supply is cut off entirely, the pistons running *in vacuo* until the demand again causes the pressure to fall. As the air supply is not throttled the system is a higly efficient one. Special tests have demonstrated that the power required to run the compressor light

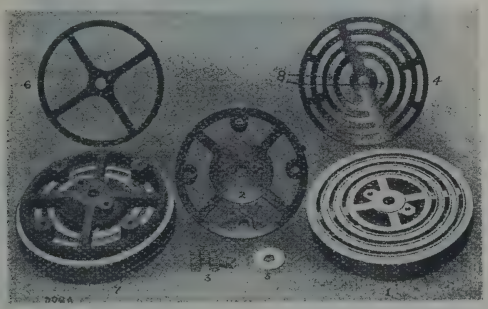

FIG. 7.—Details of Valves used in Belliss Compressors.

may be only 6 per cent. of the full power, and under 9 per cent. for the compressor and motor combined.

One of the chief points in the design of these compressors is the air valves. These are of the Rogler-Hoerbiger patent thin plate type, fig. 7, devised as the result of experience gained during the construction of the Simplon Tunnel, and which have come to be recognised as one of the best types of valves for air compressors. The valves consist of light discs of tempered

steel, perforated to give a multiple opening and falling on a cast-iron grid with suitable cushion and guard plates above. These valves are very reliable, noiseless in action, and a minimum amount of power is lost in operating them.

The Bellis compressors are also made with self-contained steam cylinders, controlled by the makers' patent relay type air governor, designed to vary the speed of the compressor in accordance with the demand for air, there being also a centrifugal governor directly connected to the crankshaft to prevent the speed under any conditions exceeding a predetermined maximum.

The 'Holman' Single-Stage Air Compressor.

(Holman Bros., Camborne)

The Holman P.I. type compressor, fig. 8, has one large outlet valve A in the cylinder cover and one large suction valve B in the piston head. It is a uniflow type engine, i.e. the air is not reversed in direction, but passes through the cylinder from bottom to top. The intake air is drawn direct from the atmosphere through a large inlet port in the side of the cylinder C.

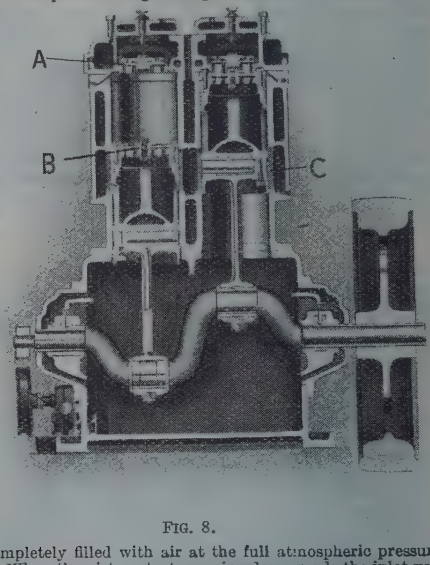

Fig. 8.

The cylinder is completely filled with air at the full atmospheric pressure at every suction stroke of the piston. When the piston starts moving downwards the inlet valve remains behind due to its inertia, and the air immediately enters the cylinder. No partial vacuum whatsoever is caused.

The size of each valve is fixed only by the volume of air passing. Owing to the space available, there is no restriction of the portways, and there is no wire drawing on either the suction or delivery strokes.

Ports are eliminated, the valves being inside the cylinder.

As there is only one valve in the cylinder cover, there is ample space for a large water jacket. The temperature of the delivery valve is exceptionally low for single-stage compression, and valve breakages are eliminated.

The valves are a high-grade steel in the shape of thin plates with portways. They are ground with very great care, so that they bed perfectly on their seatings; they are automatic in action, are unable to rotate, and, therefore, bed always in the same place; they cannot get out of adjustment.

Owing to the large size of the valve ports the lift is small: this, coupled with extreme lightness of the valve plates, reduces the wear and noise to a minimum.

By removing five nuts the delivery valve is withdrawn, the removal of one more nut freeing the suction valve. No water connections need be broken, nor need intake and delivery connections be removed.

The largest machine of this design has a capacity of 272 cub. ft. per min. Above this size the two-stage double-acting principle is adopted. Forced lubrication is used throughout.

The New Holman Rotary Air Compressor.

(Hele-Shaw Beacham System.)

(Holman Bros., Camborne.)

This compressor, fig. 9, is a development of the H.S. Rotary Oil-Pump, which has been in use for some twenty years; it is the joint invention of Dr. H. S. Hele-Shaw, F.R.S., and Mr. T. E. Beacham, B.Sc.

One of the outstanding features of the compressor is the cylindrical body, which rotates round a fixed cylindrical valve. The reciprocal movements of the pistons are effected by means of an eccentric floating ring, which is carried on ball-bearings and rotates freely with, though it is not fixed to, the cylinder body. By combining with this mechanism a special means of sealing and lubrication, the compressor has been made capable of continuous running at a speed of 1,000 or more revolutions per minute in ordinary practice; and in a recent experiment a Holman Rotary Compressor was successfully driven at 2,300 r.p.m.

Details of Construction.

There are two low-pressure and two high-pressure cast-iron cylinders, the sides of each being pierced by slots which receive the gudgeon pins. The centre of the casting is bored to fit the central valve. The ports in the cylinders are conical in form; those of the low-pressure are to the left, and those of the high-pressure to the right, of the centre line. The valve, though

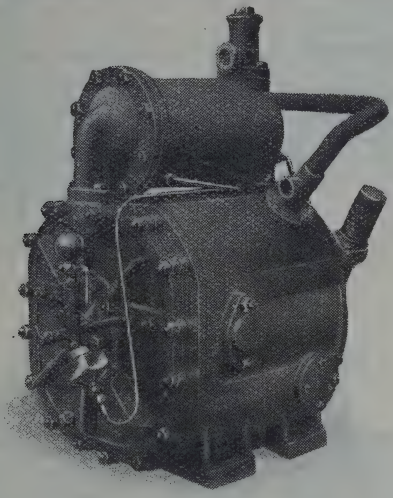

Fig. 9.

of somewhat intricate design, works very efficiently. The automatic lubrication of the valve prevents direct contact with the cylinder casting, so that wear and tear are reduced to a minimum.

A special feature of the low-pressure pistons is a conical protuberance at the base, which fits into a hole of similar shape in the cylinder casting. Grooves in this projection pick up oil from the cylinder walls and supply it automatically to the gudgeon-pin bearings.

The driving shaft is screwed to the cylinder. It is bored at the end to receive the roller-bearing which supports the valve, and is perforated to facilitate lubrication of the ball-bearings and the passage of suction air to the valve.

All rotating parts are enclosed in cast-iron cylindrical casing, provided with a water jacket and carrying the two floating rings, the driving shaft bearing and the inter-cooler and after-cooler.

The two coolers are unique in that they are not of the usual pipe form. They are enclosed in one aluminium casting, the lower portion forming the inter-cooler and the upper portion the after-cooler. The water, which passes between the cooler and the casing, is so directed that the coolest water comes into contact with the coolest air.

Another novel feature is the system of lubrication. The inflowing air is saturated with oil, thus ensuring entirely 'fool-proof' lubrication, perfect air seal round the valve and pistons, and the absorption of heat from the air during compression. A special device, the oil eliminator, into which the air passes from the after-cooler, removes the oil from the air by means of a wire filter, from which the oil passes into the pump.

The volumetric efficiency of the Holman Rotary Compressor is exceptionally high, and the isothermal efficiency is practically constant over the whole range of delivery pressures.

In the smaller sizes the compressor is readily portable, and is very compact.

The compressor has been used by the Admiralty and the Air Ministry.

The Holland 'SLM' Rotary Air Compressor.

(Bernard Holland & Co., 17 Victoria St., London, S.W. 1.)

(1) This Rotary Air Compressor, figs. 9A, 9B, consists essentially of a fixed casing or stator in which is a rotor fitted with blades free to move radially. As the rotor is less in diameter than the bore of the stator or casing and is placed eccentrically within it, there is a crescent-shaped space between

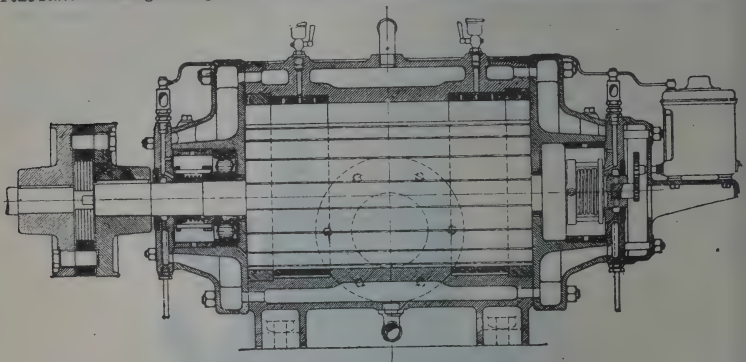

FIG. 9A.—The Holland 'SLM' Rotary Air Compressor.

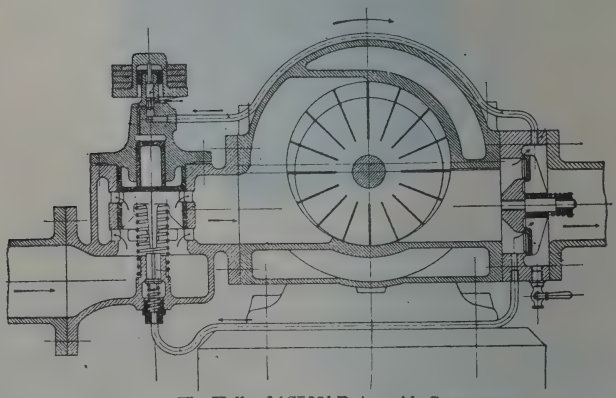

FIG. 9B.—The Holland 'SLM' Rotary Air Compressor.

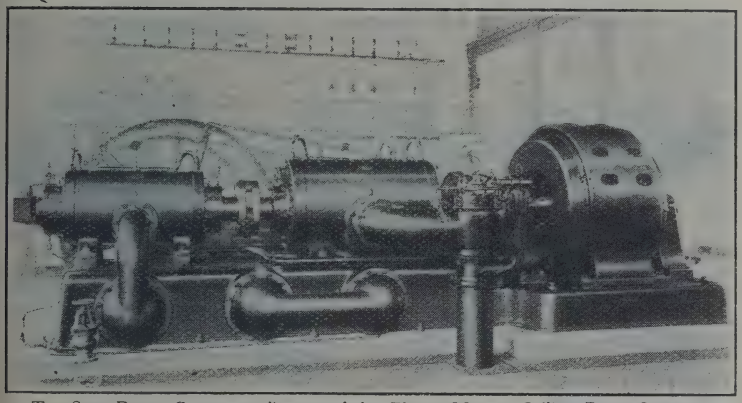
them. When the rotor is revolved, the blades, maintained by centrifugal force in contact with the casing, divide the crescent-shaped space into cells, which, each in turn, expand from a minimum to a maximum cubic capacity (suction period) and then decrease to a minimum cubic capacity (compression and delivery period).

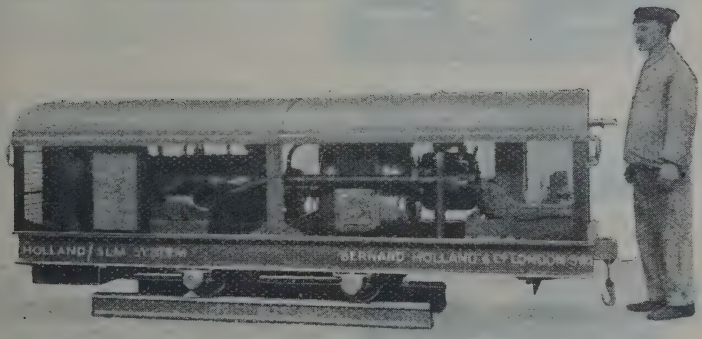
Floating rings, one near each end of the rotor and revolving in unison with it, take the greater part of the thrust of the blades, so restricting and controlling their pressure on the wall of the casing; the consequent low friction and the absence of reciprocating parts and valves allow of this compressor being run at high speeds of revolution without vibration or perceptible wear after long use.

ROTARY AIR COMPRESSORS

Holland S.L.M. System



Two-Stage Rotary Compressor direct coupled to Electric Motor in Colliery Power Station. Capacities up to 7,000 cub. ft. per min.



Portable Rotary Air Compressor for in-Bye Working with explosion-proof Electric Motor.

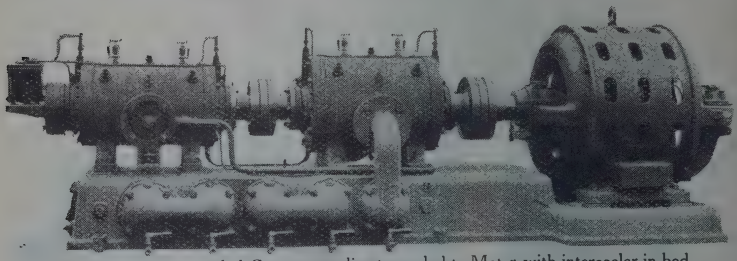
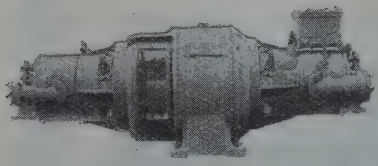
ROTARY AIR COMPRESSORS *and* VACUUM PUMPS

Holland S.L.M. System for all Industries



Two-Stage water-cooled Compressor direct coupled to Motor with intercooler in bed. Pressures up to 150 lbs. per square inch.

Single-Stage water-cooled, belt-driven Compressor. Pressures up to 60 lbs. per sq. inch.



Two-Stage Rotary air-cooled Brake Compressor, with Motor in one unit.

Two-Stage Vacuum Pump in one Casing. Vacuum up to 99·9 per cent.

BERNARD HOLLAND & CO.

17 Victoria Street, LONDON, S.W.1.

F. 1263

Metallic glands of special design dispense with the use of stuffing-boxes and packing. The lubrication is by pump, and is automatic.

Air-cooled single-stage compressors are made for pressures up to 10 lbs. per sq. in., and water-cooled single-stage machines for pressures up to 60 lbs. per sq. in. Water-cooled two-stage machines are supplied for pressures up to 150 lbs. per sq. in. and, dependent on size, up to 200 lbs. per sq. in. They are made in a number of standard sizes ranging from 6 cu. ft. to 4,000 cu. ft. delivery of free air per minute. For certain duties much larger units can be built.

The pumps are particularly suitable for continuous duty, coupled direct to electric motors and other fast-running prime movers; they are also arranged for belt and chain drive. They occupy little space, run without vibration, and need but inexpensive foundations.

(2) These machines can be so arranged as to perform the dual service of compressing and exhausting, one and the same machine being operated, at will, either as a compressor or as a vacuum pump. (See p. 1265).

Air-Compressor Packing.

'BRITIMP' BRAND HOLLOW RING PACKING.

(*British Metallic Packings Co., Ltd., 7 Princes Street, Westminster, S.W.* 1.)

This packing is largely used for high-pressure air and gas compressors, also for water-pumps, hydraulic accumulators, stop valves, emergency valves, expansion joints, gun recoil chambers,

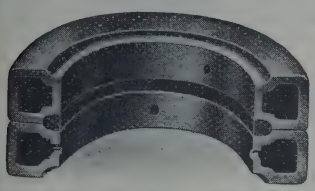


FIG. 9C.

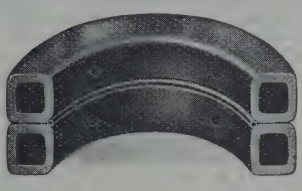

FIG. 9D.

etc. The packing consists of hollow circular rings filled with graphite. The inner walls of the rings contain small holes through which the graphite is squeezed, thus providing the necessary lubrication. The rings are made in two forms, as shown in figs. 9C and 9D.

See also pp. 1805, 1844, and 1949.

Air-Compressor Lubrication.

An oil suitable for air-compressors should always be highly filtered, because such oil will have a minimum tendency to form carbon deposits. Oils compounded with vegetable or animal oils are quite unsuitable for air cylinders.

Use only a straight-run, highly filtered, pure mineral oil of the lowest natural flash test consistent with the viscosity necessary to lubricate the cylinders and provide a proper piston seal.

The correct viscosities (worked out by the members of the Compressed Air Society, U.S.A., all of whom are builders of air-compressors) are given in the following tables, showing the proper specifications for both paraffin and asphaltic oils of various viscosities.

PHYSICAL TESTS OF PARAFFIN-BASE OILS. (*W. F. Osborne.*)

Cooling Water for Air Compressors.

Cooling water for cylinder jackets, cylinder heads, and intercoolers should always be turned on before the compressor is started. In case of stage compression, the greatest efficiency is obtained with the outlet water from the intercooler at a low temperature. The water supply to air cylinders and intercooler should be independent of each other, and the flow controlled by a valve on the inlet. The water should be shut off when the compressor is stopped, and in freezing weather all jacket drains should be opened. Outlet water should flow into open funnels so that frequent temperature readings can be made, a rise in temperature indicating deficient cooling, carbonised discharge valves, or leaking piston rings. The use of the thermo-siphon cooling system is not recommended.

NOTE ON AIR-COMPRESSOR OPERATION.

A bad practice in air-compressor operation is to put the air-discharge pipes through the intake duct. This serves directly to defeat the gain of the cool duct, because the hot discharge pipe heats the incoming air. On one such installation the incoming air was heated 6° F. by the presence of the discharge pipe in the intake duct. In this case there was a direct throwing away of about 1½ per cent. of power, which amounted to throwing away 11½ lbs. of coal every time 1,000 lbs. was shovelled into the furnace, day in and day out. In estimating such a heating loss a rough figure is 1 per cent. loss for each 5° F. intake-temperature rise.

VACUUM PUMPS.

THE BAILEY PATENT SLIDE VALVE 'DRY' VACUUM PUMP.

(Sir W. H. Bailey & Co., Ltd., Manchester.)

In the 'K' Vacuum Pump the slide-valve is without a stuffing-box, and the spring delivery valve is not carried by the slide-valve, but works vertically on a stationary seat, easily accessible even when the machine is running. By this arrangement the slide-valve does not run in the interior of the valve chest, but on the outside of it, and is, consequently, easy to fit and adjust; it has no stuffing-box to its spindle.

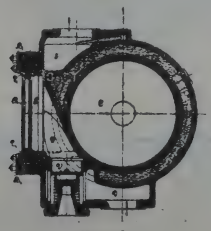

FIG. 9E.

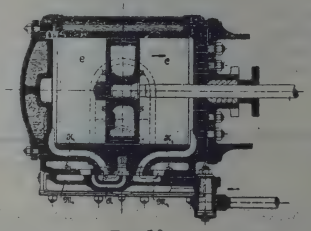

FIG. 10.

Fig. 9E shows a transverse section, and fig. 10 a longitudinal section of the standard air cylinder of the 'K' pump. The cylinder and back covers are water-jacketed, the front cover is cast in one with the cylinder, and a joint between the cylinder and the frame is avoided. In the larger sizes the front cover is water-jacketed.

The action of the valve is as follows :—

The air or gases enter by the suction pipe S and pass to the spaces S1 and S2. In fig. 9E the piston is passing towards the left-hand side and draws air into the cylinder from S2 through the space M2 and the port K2. At the same time it discharges the air drawn in during the preceding stroke by K1, P, and D, the slide-valve being set in relation to the crank so that the spaces S1 or S2 and D are put into communication at the right moment with the corresponding ends of the cylinder. Besides the ports M1 and M2, through which the gases pass into the cylinder, and the port P1 through which they are discharged, the slide-valve has a compensating or equalising port A which communicates between the discharge side of the piston and the suction side, thus equalising the pressure. When the piston has reached the dead point this port opens, for an instant of time, the communication between the two sides of the piston, the cylinder being cut off from the inlet and outlet by the slide-valve. The tension or pressure in the clearance space is thus reduced almost to the suction tension or pressure, and the piston can now draw air in much sooner, the effective suction stroke or volumetric efficiency being thereby increased. In addition to the slide-valve there is a spring valve V. The slide-valve governs the beginning and the end of both suction and discharge strokes. The spring valve has no effect on the volumetric efficiency of the pump, as without it the same volume would be drawn in, but it is necessary in order to reduce the power required to drive to the lowest possible limit. The slide-valve opens the suction and discharge at the beginning of each stroke and closes at the dead point so that the pump can be used for any degree of vacuum. The opening of the discharge port at a time when the air or gases are not yet compressed to atmospheric pressure would permit the air in the discharge pipe to flow back into the cylinder, causing back pressure and loss of power. The spring valve prevents this, as it separates the external air from the cylinder and prevents it from entering the cylinder when the slide-valve opens the discharge. When the air or gases in the cylinder are compressed to atmospheric pressure the spring valve opens automatically and the discharge commences. The influence of the spring valve therefore only affects the power for driving as previously stated ; it works vertically, is always accessible even when the machine is running, and is noiseless.

The single type pumps will maintain a vacuum of over 29·8 ins. of mercury when exhausting from a closed vessel. When a higher vacuum is necessary, the Bailey Double Vacuum Pump is recommended. This pump will maintain a vacuum of over 29·95 ins. of mercury at normal temperature and with a barometric pressure of 30 ins.

These pumps are particularly suitable as air pumps for condensers for steam engines, central condensation plants, cooling towers, condensers for evaporating plants, vacuum drying plants, distillers, filtering plants, etc.

The Holland 'SLM' Rotary Vacuum Pump.

(*Bernard Holland & Co.*, 17 *Victoria St.*, *London*, *S.W.* 1.)

This machine is rotary and is similar in general design to the Holland 'SLM' Compressor; it runs without vibration at the same high speeds of revolution and possesses all the characteristics of that machine, including the ability to perform, at will, the dual service of exhausting and compressing when arranged with the appropriate inlet and outlet piping. The single-stage air-cooled pumps will maintain a vacuum of 60 per cent. or 18 ins. of mercury with a barometric pressure of 30 ins., and under the same conditions the single-stage water-cooled pumps will produce a vacuum of 96 per cent. or 28·8 ins. of mercury, and the two-stage water-cooled machines, when exhausting from a closed circuit, will maintain a vacuum of over 99·9 per cent. or 29·97 ins. of mercury.

These machines, like the compressors, will run continuously with little attention, and maintain their efficiency after long use.

See also p. 1262.

Snifting Valves.

These valves open for the purpose of allowing the passage of air, but close if liquids attempt to pass; they are used in hydraulic systems, and also in motor-cars. In a simple form the arrangement is shown by fig. 11.

B is a light float with a leather washer at the top ; O is an outlet pipe ; X is the pressure system. Air is free to pass in and out, but if liquid is passing out, B is carried up and seals the outlet pipe.

In connection with air vessels for pumps, a snifting valve is utilised to recharge such with air; two cocks may be used, one at the top and one at the bottom of the vessel, so

that water may be drawn off below and air re-admitted above. If it be desired to admit it automatically while at work, a 'snifting valve,' a separate air-pump, or an air-injector may be adopted. The valve, fig. 12, is placed between the suction and delivery valves, and

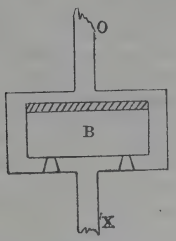

FIG. 11.

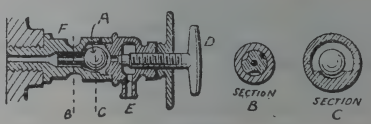

FIG. 12.

consists of a gun-metal chamber, F, containing a ball, A, which rolls backward and forward on account of the pump stroke. When rolled leftward, air is drawn inward at E, while the escape of water on return stroke is prevented by a rightward roll, and the whole may be put out of action or adjusted by a screwed plug, D.

PNEUMATIC DESPATCH TUBES.

TUBES.

The tubes used in the Pneumatic Despatch Service (telegrams only) of the British Post Office are 3, 2¼, and 1½ inches in diameter, the 2¼-inch being the size in most general use. The tubes are manufactured in lengths of about 28 feet. The tubes are of lead, and are enclosed in cast-iron pipes for mechanical protection. Each length of lead pipe is laid in a wooden trough as soon as manufactured, so that it may be handled without fear of bending. A tightly fitting polished steel 'mandril,' 1 foot long, and of the exact gauge of the tube, attached to a strong chain, and lubricated with soft soap, is then drawn through the entire length of the tube. This operation insures the tube being smooth, cylindrical, and uniform throughout. The jointing of the lead tubes is effected as follows: Previous to the placing of the tubes in the trench, a strong chain is passed through it, and a polished steel mandril, 6 inches long and slightly less in diameter than the diameter of the tube, is heated and attached to the chain, and pushed half its length into the end of the tube already laid; the new length of tube is then forced over the projecting end of the mandril until the tube ends (which have been previously cut flat) butt perfectly together; a plumber's wipe joint is then made. By this means the tube is made perfectly air-tight, and the mandril keeps the surface of the tube under the joint as smooth as at any other part of its length. After the joint has been completed, the mandril is drawn out by the chain attached to it, the next length is drawn on and the process repeated.

CARRIERS.

The carriers in which the messages are placed consist of a cylindrical tube of gutta-percha covered with felt: a 'skirt' projects beyond the open end of the carrier. The pressure behind causes the skirt to expand until it exactly fits the tube and thus prevents the air leaking past. The front of the carrier is provided with a buffer or piston, formed of several discs of felt, which exactly fits the tube. To prevent the messages getting out of the carrier, the end is closed by an elastic band, which can be stretched sufficiently to allow the messages to be put in.

The length, over all, of a carrier for a 2¼-inch tube is 6¾ inches; the inside measurements of the gutta-percha tube or message holder being—length 4½ inches, diameter 1¼ inches. The weight of such a carrier when empty is a little over 3 ounces.

The 3- and 2¼-inch carriers will, on the average, take 65 and 25 messages respectively.

The speed of the carrier may be roughly stated to range from 20 to 30 miles an hour for tubes not exceeding a mile in length.

WORKING PRESSURE AND VACUUM.

The standard pressure is 10 lbs. per sq. in., and the standard vacuum 6½ lbs. per sq. in.

For a given effective pressure, carriers travel most rapidly in pressure tubes when the air supply is *intermittent*, *i.e.* when the message tube is only connected with the compressed air mains during such times as carriers are actually traversing the tubes. The reason of this is, that

F. 1267

the compressed air with which the portion of the tube in front of the carrier is full, and which has to be displaced by the advancing carrier, weighs more than the uncompressed air, and consequently requires a greater amount of power to move it. The difference in the two cases is, however, not great, but the higher the pressure the greater is the difference in speed due to this cause. With 6 lbs. pressure, the carrier takes only 3 per cent. longer time with continuous than with intermittent working, whilst with 14 lbs. pressure it takes nearly 6 per cent. longer time.

In the case of carriers propelled by the exhaustion of the air, if the exhaustion is not commenced until the carrier is inserted at the further end, then the carrier commences to move as soon as the exhaustion at that end reaches a few ounces only, and the full exhaustion effect is not felt until the carrier has been moving for some time. When, however, the exhaustion is continuous the carrier on its insertion practically starts off under the full pressure: hence its speed is greater than in the first case. The continuous system of vacuum working, where one tube is used for the 'up' traffic (i.e. the traffic from the distant to the central or 'power' station) only, is easily effected, whether the traffic is heavy or light; but the intermittent system for the 'down,' or pressure working, which, as pointed out, gives the greatest speed, cannot always be followed out, as during the busy hours of the day the carriers have to be despatched in such quick succession that the current of air in the tube is practically continuous.

Power Required to Work Tubes.

The actual power required for working *continuously* the tubes at a pressure of 10 lbs. per square inch (the standard pressure) is, theoretically, 3·35 horse-power for a 2½-inch tube 1 mile long; but in practice 50 per cent. requires to be added to allow for losses from various causes, *i.e.* the actual horse-power should be 5. With 10 lbs pressure the time occupied in the transit of a carrier through a tube 1 mile long is 2½ minutes.

In order to neutralise the intermittent action of the pumps, and ensure a uniform flow of air, reservoirs or 'containers' are provided. These are arranged to have sufficient capacity to give out a reserve supply when the load on the tubes becomes abnormal, as occasionally happens.

For a given transit time the actual horse-power required is much less in the case of vacuum than in the case of pressure working. Thus, for example, the transit time for 10 lbs. pressure is the same as for 6½ lbs. vacuum, but the horse-power required in the two cases would be as 1·83 to 1. Inasmuch, however, as the tubes cannot practically be worked only by vacuum, the calculations for transit time and horse-power must be based on pressure working. The actual power necessary must be largely governed by local conditions, and no definite rule can be laid down. The power required to work any tube or number of tubes is usually computed, however, on the estimated traffic in carriers per hour which each tube is required to carry. This figure multiplied into the volume of the tube and divided by 60 gives the volume of air swept out per minute (if there is a number of tubes the figures are of course aggregated), and this affords the capacity of the pump at the required pressure.

Pumping Machinery.

The air compressors used for this system are driven by electric motors, oil, steam, or gas engines, and are provided according to the present standard practice with one or more cylinders arranged to draw from the vacuum container and compress the air thus drawn into the pressure container. Automatically controlled auxiliary valves are interposed in the inlet and delivery mains of the pump. They are controlled pneumatically by means of a by-pass connection with the pressure container in such manner that if (*a*) the pressure in the pressure container is low and the vacuum in the vacuum container high, so that the pump is deprived of air to compress, the auxiliary inlet valve on the vacuum main opens to atmosphere and admits free air for compression until the pressure in the pressure container is restored, when the valve shuts. On the other hand, (*b*) if the vacuum is low and the pressure is high, so that the pump would have to discharge against considerable back pressure the air it exhausts from the vacuum container, the auxiliary valve in the pressure main opens to atmosphere until the vacuum is restored. A non-return valve on the container side of each auxiliary valve prevents the loss of pressure or vacuum whilst either auxiliary is open to atmosphere. This system, besides economising in plant and space, absorbs and utilises certain losses which are inevitable with independent pumping for both services.

Transit Time.

Table I. enables the transit time for any diameter and length of tube at any pressure to be calculated, and from Table II. can be ascertained the pressure required to drive a carrier through any tube in any time. The chart, fig. 13 (p. 1270), based on Table I., shows the Transit Time variation for different lengths of tubes of three sizes, 1½ in., 2½ ins., and 3 ins., each worked at 10 lbs. pressure.

I.—Tables for calculating Time of Transit of a Carrier through a Tube.

Formula: $t = \cdot00872\sqrt{l^3} \times \frac{1}{\sqrt{P}} \times \frac{1}{\sqrt{d}} = A \times B \times C$ secs.

$A = \cdot00872\sqrt{l^3}$.

Example ; Required, the pressure, P, to drive a carrier through a tube 5 ins. in diameter (C_1) and 2.000 yds. long (A_1) in 200 secs. (B_1). $P = 608{,}000 \times \cdot0000250 \times \cdot200 = 3$ lbs.

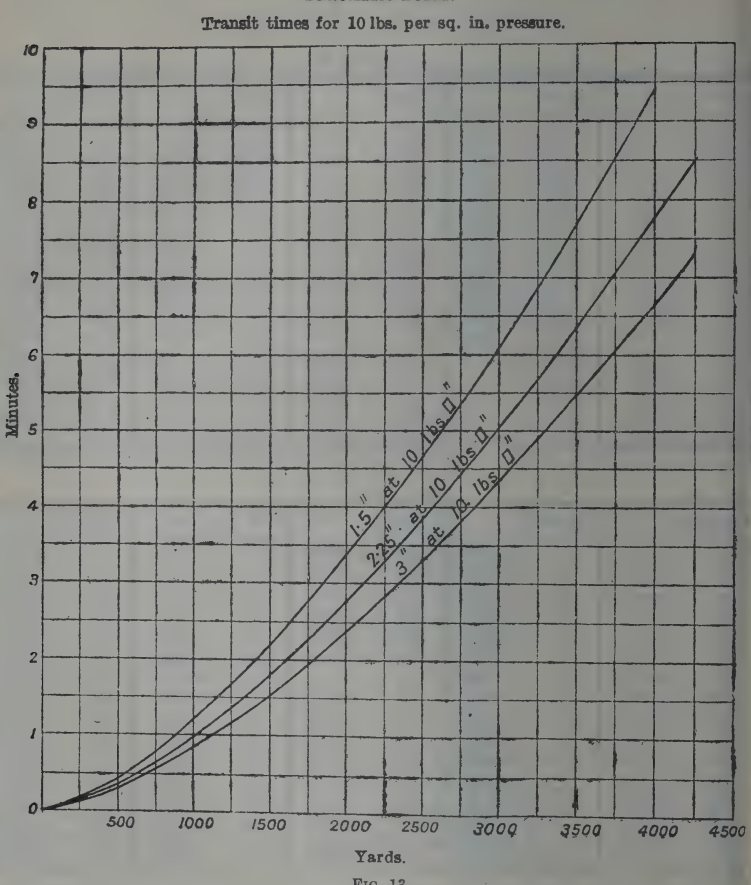

FIG. 13.

PNEUMATIC HOUSE TUBES.

These are, in the British Post Office Service, usually of brass or copper, and in some cases are operated on lines similar to the foregoing system, but considerable modifications have been introduced.

A very general system for warehouses is a circular one with loops into the various apartments which it is desired to connect.

The air is continually circulated by means of a blower of the Roots type which is joined at one end of the tube, whilst the other is open to atmosphere.

Carriers are despatched from a station by being inserted in the 'return' pipe of the loop and are received on the 'flow' pipe, suitable receiving apparatus being provided for the interception of a withdrawal of the carrier without interrupting the flow of air, which is made to travel through a by-pass.

SECTION XXIV

REFRIGERATION—REFRIGERATING MACHINERY—ICE MAKING—COLD STORAGE.*

(Contributed by Hal Williams, M.I.Mech.E., M.I.E.E., Consulting Engineer, and A. G. Clausen, A.M.I.Mech.E.)

Refrigeration, or the mechanical production of low temperatures for commercial use, is a process of removing heat at a low level and discharging it at a high level on the thermometer scale.

In a steam-power plant heat is applied to evaporate water in a boiler; a small proportion of the heat supplied is converted into useful work in the engine, and the balance which cannot be utilised is rejected to the condensing water.

A refrigerating machine is simply a reversed heat engine; the cold air machines are now obsolete, and in all modern plant heat is taken up by the evaporation of some suitable working fluid termed the 'refrigerant,' and more heat is applied, generally in the form of power, to compress the resulting vapour to such a pressure that it can be condensed.

The sum of the heat taken up by evaporation and that added as power is then discharged in a condenser, to water of the prevailing normal temperature, the refrigerant is condensed, and as a liquid is in a state to complete the cycle of operations.

The performance of a refrigerating machine is the ratio of the number of heat units abstracted to those applied as power, and for a reversible cycle with a perfect fluid is $\frac{T_1}{T - T_1}$

where

T = absolute temperature of condensation;
T_1 = " " " evaporation.

A refrigerating machine working on the compression system—which is practically universal—is shown diagrammatically in fig. 1 (see p. 1274) and consists of four essential parts:

(1) The evaporator or refrigerator, in which the refrigerant boils or evaporates at a low pressure and temperature.
(2) A gas pump or compressor to withdraw the vapour formed in the evaporator and compress it to such a pressure that it can be condensed by the water supply available.
(3) The condenser in which the compressed gas is condensed at a high pressure.
(4) The regulating or expansion valve, provided with fine adjustment to control the rate of flow of the condensed liquid from the condenser into the evaporator.

Starting with the liquid refrigerant in the condenser, the thermal cycle is as follows:

The liquid at condenser pressure and temperature is permitted to flow through the regulating valve into the evaporator.

On passing the valve a proportion immediately evaporates, taking up its latent heat from the remainder, which in this way is cooled to the evaporator temperature.

The remainder evaporates at constant pressure and temperature, taking up its latent heat from the air, brine, water, or other substance that is in contact with the exterior surface of the evaporator, and which is correspondingly reduced in temperature.

The proportion of the liquid evaporated to cool the remainder to the temperature of evaporation is not available for refrigeration, and represents a loss as compared to the ideal or reversible cycle.

The liquid should therefore be cooled to as low a temperature as is practicable by ordinary means before passing the regulating valve, and its specific heat, considered as a fraction of its latent heat, should be low.

The vapour leaving the evaporator may be either:

(*a*) In a dry saturated state;
(*b*) Slightly superheated, or having its temperature a few degrees above its saturation temperature.
(*c*) In a wet state, or carrying with it some particles of unevaporated liquid.

With (*a*) and (*b*) the condition of working known as 'dry compression' is obtained and the work of compression, converted into heat, raises the temperature of the refrigerant so that it is discharged from the compressor in a superheated condition.

---

A small proportion of the heat of compression can be absorbed by water jackets on the discharge side of the compressor. Owing to the low initial temperatures, complete water jacketing cannot be used as with air compressors, as it would cause losses through initial superheating.

With (c) the heat of compression is either partially or wholly taken up by the evaporation of the entrained liquid, and the state of working known as 'wet compression' is obtained when the incoming vapour carries just sufficient liquid to maintain the refrigerant during compression at the temperature corresponding to its saturation pressure.

In practice the refrigerant is as a general rule at some point between the states giving either completely dry or wet compression.

In the condenser the gas, if superheated, must first be cooled down to its saturation temperature, when the process of condensation proceeds.

In order to permit the transfer of heat, the temperature of evaporation must be below that to which the air or brine is to be cooled, and similarly the temperature of condensation must be above that of the cooling water used.

The greatest efficiency is obtained when the temperature of evaporation is as high and the temperature of condensation is as low, as possible, so that the surfaces for heat transfer should be large to keep the necessary differences small.

The refrigeration effected per pound of refrigerant can be obtained directly from the tables of properties of the various fluids, by deducting the total heat of the liquid at the condenser temperature from the heat content of the saturated vapour at the evaporator temperature.

The volume of gas that must be pumped by the compressor can be obtained directly in the same way.

The amount by which the actual swept volume of the compressor must be greater than the net volume of the gas, will depend upon the characteristics of any particular compressor and the conditions of working, and averages about 25 per cent.

The power required to drive the compressor can be obtained directly from the Mollier or from the entropy diagrams, or from indicator diagrams for the compressor.

The heat that must be transferred to the condensing water is the sum of the heat abstracted or effective refrigeration, and the heat equivalent of the work done in compression.

The quantity of water required will vary directly with the permitted rise in temperature.

The selection of a working fluid is governed by its limits of pressure and volume over the normal range of temperatures, its critical pressure, and the relative values of its specific heat as a liquid and its latent heat.

Other factors are its action, if any, on the materials used for the construction of machinery or on lubricating oils, its poisonous properties, and its inflammability.

There are many fluids that can be used, but by far the most important are Ammonia and CO_2. Sulphuric ether was often used in the early days of refrigeration, and SO_2 has been employed to a considerable extent on the Continent of Europe.

SO_2 methyl-chloride, occasionally ethyl-chloride, and other fluids, are also used for the very small machines of the household type that are now made in large numbers.

Ammonia is generally considered to be the most satisfactory and economical refrigerant. It has a high latent heat, and over the normal temperature range the pressures and sizes of parts are comparable to ordinary steam and air compressor practice.

The gas has a highly pungent odour and is irrespirable, so that great care must be exercised in working or in overhauls, to prevent dangerous leakages.

It is exceedingly soluble in water, and one volume of water at 60° F. will absorb 600 volumes of gas.

Ammonia attacks copper and its alloys, so that none of these must be used for parts of the machine with which it comes in contact.

The figures given in Tables II. and III. are for compressors working with dry or practically dry compression. They represent the average results that are obtained with machines of moderate size, but the variations in performance and power naturally vary to some extent with the characteristics of different makes.

With wet compression, both the number of B.Th.U.'s abstracted and compressor I.H.P. are reduced per unit compressor volume, and theoretically the performance, or ratio of $\frac{\text{B.Th.U.'s}}{\text{I.H.P.}}$ is slightly superior, though in practice dry compression gives the best results.

Carbonic Acid Refrigerating Machines.

CO_2 occupies a unique position in the group of fluids used for refrigeration in that its critical temperature (88·4° F.) often comes within the working range; also its specific heat is high, and its latent heat relatively low.

Its efficiency with condensing water at about 50° F. is but little inferior to that of the ammonia machine, but falls away more rapidly with an increasing condenser temperature. There is, however, no break in the curves of capacity at the critical temperature.

CO_2 is inodorous, and it is stated that air containing up to 8 per cent. can be inhaled without danger, though at higher percentages it causes stupefaction and suffocation.

The quantities used in machines are, however, such that even if the whole charge were to escape, in any ordinary situation, it is hardly likely to produce a dangerous concentration, and on this account the Board of Trade regulations permit CO_2 machinery to be installed in the engine-room or similar space on board ship, whereas ammonia machines must be housed in a special deck-house.

CO_2 does not attack any metals, so that condensers can be constructed of copper piping, and these advantages have given it a predominant position for marine refrigeration.

Although the pressures are high, the diameters of all parts are small, so that there are no constructional difficulties.

32	33·29	1·22	1·50	1·90

The figures given in Tables V. and VI. are for ordinary CO_2 compressors working with dry compression. They represent the average results that are obtained with compressors of moderate size, but the variations in performance and power naturally vary to some extent with the characteristics of different makes.

To obtain the best results in working, a CO_2 machine should be run with the suction gas in a dry saturated state, or even slightly superheated. When leather piston and gland packings were used this was impracticable, as the leathers were burnt by the temperatures reached with dry compression. All modern CO_2 machines have piston rings and metallic gland packings, so that there is now no difficulty in running a CO_2 machine to give the best results that can be obtained.

With high condensing temperatures the performance of a CO_2 machine can be appreciably improved by permitting the cooling of the liquid by its own partial evaporation to take place in two stages.

The compression also takes place in two stages: in the first the vapour from the liquid that has effected refrigeration, plus that from the second stage of the partial evaporation for liquid cooling, is compressed to the pressure at which the first stage of partial evaporation ends, when the whole of the vapour is compressed to the condensing pressure.

Other Refrigerants.

Both the theoretical and practical performance of other fluids used approximate closely to the results obtained with Ammonia, but the B.Th.U.'s extracted and compressor I.H.P. as shown in the tables should be divided by the following factors:

For Sulphur Dioxide	2·89
For Methyl Chloride	1·94
For Ethyl Chloride	6·57

The principal characteristics of these refrigerants, taken at 32° F. are:

TABLE VII.—REFRIGERANTS.

Refrigerant.	Absolute Pressure. Lbs. per sq. in.	Volume Vapour. Cu. ft. per lb.	Specific Heat of Liquid.	Latent Heat. B.Th.U.'s per lb.
Sulphur Dioxide .	22·45	3·41	0·322	156·8
Methyl Chloride .	36·63	2·68	0·467	174·6
Ethyl Chloride .	8·90	8·88	0·376	168·9

With very small machines, which receive practically no skilled attention, low working pressures are an advantage in reducing the risks of leakage, but pressures below the atmosphere should be avoided, as inward leaks of air cause difficulties in working, and any moisture carried in may combine with SO_2, forming sulphuric acid, which corrodes the parts.

Compressors.

Both single-acting and double-acting compressors are made in a large variety of designs and sizes, and during the last few years there have been great developments in high-speed forced lubrication machines suitable for direct coupling to electric motors.

With the exception of machines made by Messrs H. J. West & Co., Ltd., who employ a sleeve valve, all valves are of the automatic type, the high-speed compressors using light ring and plate valves of similar character to those developed for air compressors.

Most single-acting ammonia compressors are made of the enclosed type and work with ammonia at the suction pressure in the crankcase. The gland is of the rotary type on the crankshaft, and it is sealed with oil from the pressure lubricating pump. These machines have trunk pistons, the lower portion of which forms the crosshead, and is fitted with oil scraper rings. The upper forms the piston proper, and the suction ports in the cylinder walls lie between the limits of the travel of the upper and lower parts.

The suction valves are placed at the top of the piston, and the delivery valves in a spring-loaded false or safety head.

The arrangement enables the maximum valve port area to be provided with a minimum clearance space; the gas passes through the compressor in one direction, so that the upper portion can be effectively water-jacketed, and it is claimed that the 'Uniflow' principle increases the compressor efficiency.

The safety head is a valuable feature, as it will lift and save any risk of accident in the event of liquid ammonia or oil passing into the compressor.

These machines are always of the vertical type, and are made with from one to four cylinders.

Double-acting compressors are made both in the horizontal and vertical types, and the valves are arranged either in hemispherical end covers or round the circumference at each end of the cylinder.

Double-acting compressors usually have the gland constructed in two portions, with a central space or lantern between them. The lantern space is connected to the suction side of the compressor, so that the outer portion of the gland is subjected to the low and steady suction pressure only, and any gas leaking past the inner portion is retained in the system.

CO_2 compressors are now almost invariably machined from high carbon steel forgings to ensure strength and the necessary gas-tightness, and for the same reasons all stop valves and fittings are of mild steel and machined from the solid.

Double-acting compressors are general except in the smallest sizes; the gland is provided with a lantern which is sealed with oil at a rather higher pressure than the compressor is delivering against.

This higher pressure is obtained by using a differential piston in a cylinder, connecting the greater area to the gas delivery and the lesser area to the oil space in the gland, a small hydraulic pump being used to make up any oil leakage.

In refrigerating machinery, absolute gas tightness is essential, and it is usual to test compressors and all other parts subject to gas pressure by hydraulic test to about three times the normal maximum pressure; also to test them when immersed in water with compressed air to about one and a half times the normal maximum pressure to show up any minute leaks or porosity in materials.

Condensers.

Condensers are made in three general types:

Submerged Condensers consist of a coil, or series of coils, of piping connected to headers, contained in a tank or casing, generally of circular form, through which the water is passed.

Atmospheric Condensers consist of coils in vertical stacks, over which the water flows, erected in the open air and standing over a collecting tank. These are often made of large size, and the water continuously recirculated so that they function also as recooling towers and only require a small make up supply.

Double Pipe Condensers consist of a number of concentric pipes, arranged in series as shown in Fig. 1 (p. 1274); the water passes through the inner pipe and the gas condenses in the annulus between the two pipes. The gas and water traverse the pipes in opposite directions, so that the condenser is counter-current, and on account of the high water velocities the rate of heat transfer is high.

Evaporators.

A refrigerating machine may be used either to cool brine or water that is in turn circulated through the cooling appliances used, or it may be arranged so that the evaporator piping itself forms the cooling appliances, and this method is referred to as direct expansion.

Brine Cooling Evaporators may be either of submerged coil or double pipe construction, or for ammonia or other low pressure refrigerants they may be of shell and tube form, the ammonia evaporating in the shell around the tubes through which the brine is circulated in either one or more passes, depending upon the quantity and velocity required.

Evaporators for Cooling Water are frequently made of the open type where the water trickles over the outside of the coils to avoid the danger of freezing up in any confined spaces.

The Direct Expansion System may be applied for several purposes, but is generally only used for cooling cold storage rooms.

The piping may be fixed directly in the rooms, or nested together to form an air-cooling battery, with a fan to circulate air over it and through the rooms by a system of ducts.

This type of air cooler must have a circulation of brine maintained over the piping to keep the surfaces free from frost where temperatures below freezing-point are required, or otherwise the accumulation of snow and frost would rapidly choke it up.

Heat Transference.

The proportions of the condenser and evaporator are determined by the rates of heat transfer that can be obtained.

The rate of heat transfer is directly proportional to the temperature difference. It varies as a power of the velocity V, and may be generally taken as $V^{0.75}$.

The rate of heat transfer varies with the temperature, viscosity, density, and state of the fluids in contact with the surfaces, and to secure satisfactory operation over a long life it is necessary to allow for deposits on and deterioration of pipe surfaces.

The rate of heat transfer through iron pipe and under the conditions usually prevailing in refrigerating machinery may be taken as being approximately as follows:

	B.Th.U.'s per sq. ft. surface per hour and per 1° F. mean temp. difference.
In submerged condensers	40 to 45
Atmospheric condensers	60 to 70
Double pipe condensers with a water velocity of 3 feet per second	100 to 120
Submerged brine coolers	35 to 40
Double pipe or shell and tube brine coolers with a brine velocity of 3 feet per second	80 to 90
Direct expansion or brine piping in a room with natural air circulation only	2·0 to 2·5
Air coolers with fans and forced air circulation and an air velocity of 10 feet per second	6 to 7

To conform with general practice, pipe surfaces should be so proportioned that the mean temperature difference between the refrigerant and the brine or water is 10° to 15° F., and in the piping for rooms a difference of 15° to 20° between the air and the refrigerant or brine.

Indicator Diagrams.

The indicator diagram gives an exact measure of the indicated horse-power developed in a compressor, and if it is compared with an indicator diagram taken when the machine is new and in good condition, it will disclose any defects in working such as leaky valves or piston rings.

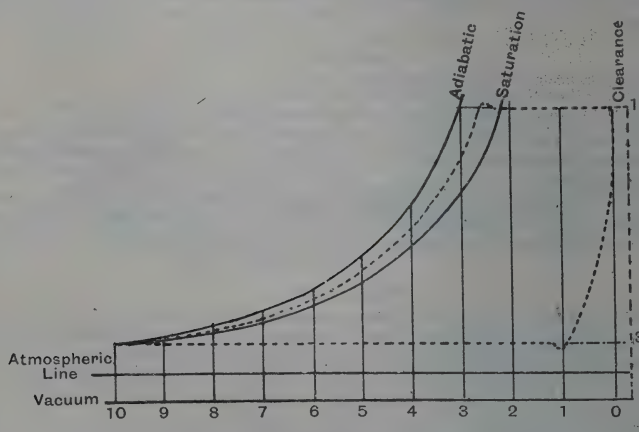

FIG. 2.

In order completely to analyse the indicator diagram, it is necessary to draw on it the curves for adiabatic compression, and for compression at saturation temperatures, as is shown in fig. 2.

With ammonia, the exponent for adiabatic compression is 1·29 and the compression curve follows the formula $P \cdot V^{1.29} = C$.

The saturation curve can easily be plotted from the volumes given in the table of properties.

The actual compression curve will lie between these two, and in the case of dry compression it will be close to the adiabatic line.

The horizontal suction and delivery lines should practically coincide with the gauge pressures. If the gauges read correctly, and the difference is more than one or two pounds, it shows that there is a restriction through the valves which may be due to either too heavy springs, the valves not working freely, or insufficient areas in the ports.

At the points where the valves open, there is always a peak on the pressure line due to the difference in pressure required to lift them from their seats, but these peaks should only be small.

The re-expansion of the gas remaining in the clearance space at the end of the stroke follows approximately the same curve as that formed on the compression stroke.

The effective swept volume of a compressor, which is indicated by the length of the suction line, is thus reduced with the proportion of the clearance volume, but as the power required is correspondingly reduced, a moderate amount of clearance does not seriously affect the performance, though it may make a considerable difference in the output of compressors with otherwise similar dimensions.

If the compression curve approaches or overlaps the adiabatic line, it indicates a leakage from the condenser side, back into the compressor through the delivery valves or the joint rings of their seats.

If the compression curve approaches the saturation line, it indicates a leakage either through the suction valves or past the piston rings.

If the diagrams from each end of a double-acting compressor are compared, and a falling away of the compression line occurs at one end only, it indicates that the leakage is at the suction valve there. If both ends are similar, it may be either the valves, the piston rings, or both that require attention.

Ammonia Absorption Machines.

Ammonia absorption machines are only used in special cases where there is sufficient live or preferably waste steam which can be utilised.

The arrangement is shown diagrammatically in fig. 3, p. 1282.

In place of the compressor the ammonia is absorbed by cool weak liquor, which, being thus enriched, is pumped into a generator or boiler, where it is heated, and the ammonia driven off into the condenser.

An interchanger is provided to heat up the cool rich liquor passing to the generator, and at the same time cool down the hot weak liquor returning to the absorber.

The small 'Electrolux' refrigerator working on the absorption system makes most ingenious use of Dalton's law of partial pressures by introducing an inert gas into what is normally the low pressure side of the system. The total pressure throughout is maintained constant, so that circulation of the liquid can be effected on the thermo-syphon principle without any moving parts. At the same time the partial pressure of the ammonia in the evaporator is low enough to effect refrigeration.

Ice Making.

The manufacture of ice is one of the principal uses of refrigeration, and the method now almost universally employed is the 'can' system, where the ice is made by placing cans or moulds containing water in a tank containing brine cooled to a temperature of 10° F. to 15° F.

When distilled and de-aerated water is used, the ice made is clear and transparent, but if ordinary water is frozen without agitation, the ice is soft and opaque, due to the minute bubbles of air dissolved in the water.

By agitating the water during the time of freezing, these air bubbles are swept off the ice surface, and the block made is clear, with the exception of a central core formed of the dissolved salts, the extent of the core depending on the hardness of the water.

Agitation can be effected by stirrers, but the best system in all except the smallest plants is that of blowing air through the water.

The time required for freezing can ice with brine at 15° F. is approximately :

Thickness of ice in inches .	3	4	6	8	10	12
Time of freezing in hours .	6	10	18	30	46	64

Ice moulds are made in a great variety of sizes to produce blocks of definite weights up to 4 cwts. each, which is a usual size for plants of large capacity, these blocks measuring about 22 in. wide, 11 in. thick, and 60 in. long.

The moulds must be made with a slight taper to enable the ice to slide out freely, and usually a number are secured together in a row, and handled as one unit by a crane.

The ice tank is arranged to contain the evaporator, which may either be of coil piping, or of the shell and tube type, and a vigorous circulation of the brine in the tank is maintained by means of a propellor or centrifugal pump.

FIG. 3.

A row of ice moulds when lifted from a tank is dipped into a thawing tank containing warm water to release the blocks of ice from the cans. These are then lifted, placed in a swinging tipping frame, and turned over so that the blocks slide out.

The empty row of moulds is then refilled with the correct quantity of water on one operation by a filling tank. One cubic foot of ice at 32° F. weighs 57·5 lbs., or 30 cubic inches weigh one pound.

In a temperate climate, and with a medium or large plant, about 230 B.Th.U.'s are required to produce one pound of ice from water at 65° F., and about 60 kw. hours are required with a motor-driven plant per ton of ice made. In warmer and tropical climates these figures are considerably increased.

Refrigerating Power.

The output of a refrigerating machine is often stated in Tons Refrigeration, and the standard American rating is then generally referred to.

One ton refrigeration is then equal to 288,000 B.Th.U.'s per day, or 12,000 B.Th.U.'s per hour when working with an evaporator temperature of 5° F. (— 15° C.) and a condensing temperature of 86° F. (30° C.).

Cold Storage.

The average temperatures maintained in cold storage rooms are as follows:

Butter—frozen	10° F. to 12° F.	Hops	28° F.
Butter—short storage	32° F. „ 35° F.	Meat—frozen	15° F. to 16° F.
Cheese	35° F. „ 40° F.	chilled	29° F. „ 30° F.
Eggs	29° F. „ 31° F.	fresh	36° F. „ 38° F.
Furs and Fabrics	30° F.	Fish—frozen	10° F. „ 12° F.
Fruit—Apples	32° F. „ 35° F.	fresh	30° F. „ 32° F.
Pears	35° F. „ 36° F.	Dried Fish—frozen	15° F. „ 16° F.
Peaches	32° F. „ 33° F.	for short storage	32° F. „ 35° F.
Oranges	45° F. „ 50° F.		

Cold storage temperatures should, as far as possible, be maintained constant without variation. Both this and the maintenance of a definite temperature are particularly important where the temperature required is in the neighbourhood of the freezing-point. For produce that is frozen hard, an exact storage temperature is not quite so important, but variations should also be as far as possible eliminated.

The refrigerating power required for cold storage rooms varies very greatly with their size, shape, insulation, quantities of warm goods brought in and methods of working, but for ordinary storage rooms is about:

Capacity of Cold Rooms in Cu. Ft.	Temperature. 30° to 35° F. Tons Refrigeration.	Temperature. 10° to 15° F. Tons Refrigeration.
1,000	0·5	0·8
10,000	2·5	4·0
100,000	12·0	20·0

These figures assume continuous operation, and for reduced hours must be proportionately increased. The surface and extent of the cooling appliances will vary with the refrigerating power required and conditions of working.

The quantity of piping fixed in a room is usually determined by empirical rules based on practical results, which vary somewhat with different makers' and users' experience and give the following averages:

Capacity of Cold Rooms in Cu. Ft.	Temperature. 30° to 35° F. Length of 1¼ in. Piping to be fixed in Stores.	Temperature. 10° to 15° F. Length of 1¼ in. Piping to be fixed in Stores.
1,000	225	450
10,000	1,125	2,250
100,000	6,000	12,000

Where other sizes of piping are used, the length is adjusted to provide a similar surface.

Calcium Brine.

Calcium Chloride Brine of a density ranging from 1·18 to 1·25 is usually employed. In estimating the weight of calcium chloride required to produce brine of a given density regard

must be had to the fact that the commercial calcium chloride contains a large amount of water of crystallisation. An approximate rule is to multiply the density by 20 and subtract 20·1, the remainder gives the number of pounds of commercial calcium chloride required for each gallon of brine of the required density; for example, take the required density at 1·20, then $1{\cdot}20 \times 20 - 20{\cdot}1 = 24 - 20{\cdot}1 = 3{\cdot}9$ lbs. per gallon of brine.

Corrosion by Brines.

An important problem of refrigeration engineers is the corrosion by brines, either sodium chloride or calcium chloride, of copper, steel, or grey cast iron. An investigation by a French authority, M. Pierre, shows that the active element of this corrosion is due to the formation of an electrolytic couple, due to the association of air, brine, and the metal, and thus the dissolution of air should be avoided by submerging the return brine pipe so that it delivers below the level of the fluid in the main container. Strong brines cause more rapid corrosion, and the presence of magnesium chloride increases the activity. Lime or soda should be used with them to neutralise the formation of hydrochloric acid.

Insulation.

The thermal conductivity of the materials used for insulation may vary to some extent with individual samples, and with all loose fillings with the density to which they are packed.

The following figures are taken from the tests made at the National Physical Laboratory for the Food Investigation Board:

Material.	Density in lbs. per cu. ft.	Conductivity in B.Th.U.'s per hour per sq. ft. per 1 in. thickness and 1° F. difference in temperature.
Cork slab	11·3	0·306
" "	12·5	0·331
Granulated cork, fine	—	0·298
" " coarse	5·3	0·326
" " "	7·3	0·345
Silicate cotton	13·0	0·302
" "	21·0	0·290
Dry charcoal	11·5	0·370
Kieselguhr	30·0	0·560
Wood—Pitch pine	42·0	1·036
Concrete	—	8·200

These figures are taken at normal cold storage temperatures. The conductivity increases slightly with an increase in temperature.

To obtain the conductivity of a compound wall, the reciprocals of the conductivities of its components must be added together, and this will give the reciprocal of the whole.

Thus, if a 6-in. concrete wall is insulated with 4-in. compressed cork slabs, the reciprocal of its conductivity

$$= \frac{1}{8{\cdot}2} \times 6 + \frac{1}{0{\cdot}33} \times 4 = 12{\cdot}85;$$

and its conductivity

$$= \frac{1}{12{\cdot}85} = 0{\cdot}078.$$

If, therefore, there is a difference in temperature of 40° F., the heat leakage would be 3·12 B.Th.U.'s per sq. ft. per hour, or about 75 B.Th.U.'s per sq. ft. per day.

It is not advisable to attempt to make any allowance for the rate of heat transfer between the air and the two wall surfaces, as while this may vary very greatly, it is in any case so relatively small an item that it does not appreciably affect the result.

In an insulated wall, the jointing material for cork slabs, the timber studding for loose fillers, and unavoidable inperfections of workmanship will make the conductivity of the material as erected rather greater than the test figures given, and the results should be increased by 10 per cent. to 15 per cent. to allow for this.

The leakage of heat through the insulated walls, floor, and ceiling of a cold store practically always forms the greater proportion of the total refrigerating power required to cool it, so it is necessary that the insulation provided should reduce this leakage to a minimum.

The first essential is that the material used should have a low co-efficient for the transfer of heat; it should have no attraction for moisture, be uninflammable, inodorous, and have a high specific heat.

It should pack well without tendency to settle and leave void spaces, and it should have no tendency to spontaneous combustion under any conditions.

Compressed cork slabs erected in cement or bitumen, and having their surfaces finished in hard-setting cement, provide the most satisfactory and permanent construction, but granulated cork and silicate cotton, or slag wool, are also largely used, and other materials that are employed are pumice stone, charcoal, kieselguhr, sawdust, and shavings.

Loose filling materials are packed between wooden studs and joists, erected against walls, floors, and ceilings, and covered by T. & G. boarding with or without waterproof paper.

An air space is often provided against external walls, the construction then being illustrated in figs. 4, 5, and 6.

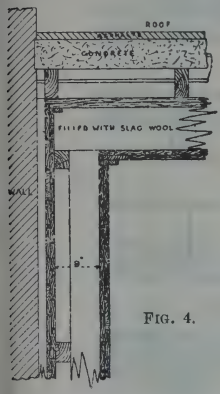

FIG. 4.

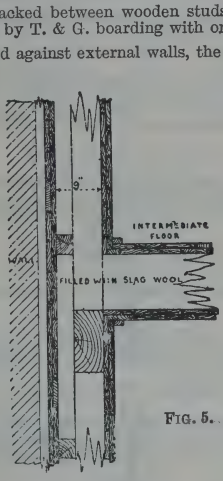

FIG. 5.

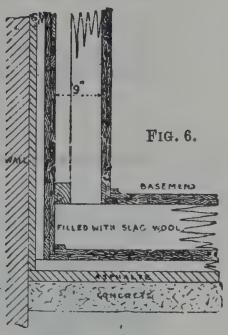

FIG. 6.

If an insulating material is allowed to become damp or sodden with moisture, its value as insulation is enormously reduced; the building or structure containing it should be impermeable to moisture, and brick walls are preferably treated with a coating of pitch or bitumen.

For large refrigerating stores for meat and other purposes the method adopted by Mr. Herbert Birkett, M.I.Mech.E., which is shown by figs. 4, 5, and 6, is one of the best that can be employed, waterproof insulating paper being placed between the matchboarding.

THICKNESS OF INSULATION.

To determine the most economical thickness of any insulating material, the cost of power to drive the refrigerating machine, which falls as the thickness of insulation increases, should be balanced against the interest on the increasing cost, and the decrease in the net or useful storage capacity.

The usual practice is to use a thickness of 4 ins. of compressed cork slabs for chill, and 6 ins. for freezing temperatures, or, alternatively, 6 and 9 ins. of granulated cork or silicate cotton. These figures are largely worked to, not entirely as giving equal insulating value, but as economical standards for the commercial thickness of cork slabs and sizes of timber.

PAPER INSULATION.

(The Willesden Paper and Canvas Works, Ltd., Willesden Junction, London, N.W. 10.)

A special description of paper known as 'Willesden' paper has for many years been largely used in the insulation of cold storage chambers. The usual method of constructing these chambers is to erect vertical studding at certain distances apart, and to cover this on both sides with grooved and tongued matched boarding, then to cover that in its turn with the Willesden paper, and over the paper to again fix another surface of matched boarding. There is then left a space between the two erections of matched boarding and paper equal to the width of the studding used, and this space is filled with some insulating material, such as charcoal, slag wool or rice husks, etc., and the work is done. The main use of the paper is to exclude air, and the Willesden material is preferred because of its durability and strength, and because it is not affected by damp nor liable to harbour fungoid growth.

'Neponset,' 'Ko-sat,' and 'Coted' are special papers of the highest grade, which are impervious to air and moisture under the severest conditions, and are largely used for cold storage insulation. They are made in rolls 36 ins. wide containing 1,000 sq. ft.

Cork Insulation.

The application of compressed cork slabs for insulation purposes is becoming more general, both in the U.S. and in England. Being in the form of slabs which are manufactured in various shapes and dimensions, they are easily fitted to the walls of the chamber. By being built together in various layers, breaking joint and cemented with a waterproof cement, they form an impermeable insulating lining to the chamber.

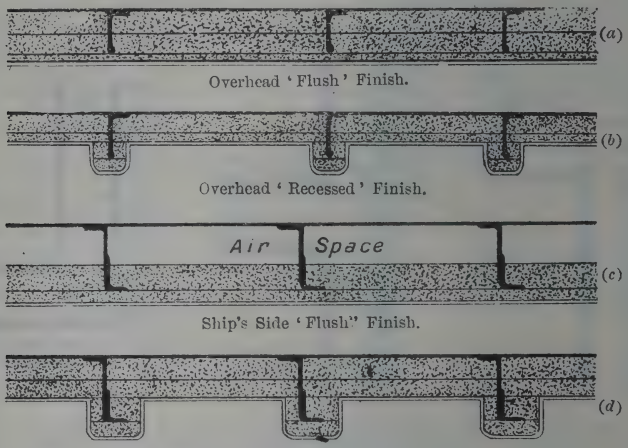

Fig. 7.—'Anderson' Jointless Insulation on Cork Slabs.

The interior facing to the chamber is usually of a special cement, preferably without joint.

With this system of insulation (fig. 7) a less thickness is required as compared with the insulating materials of a loose granular nature, and it has the further advantage of giving an increased capacity to the chamber. *Messrs. Thomas Anderson Ltd., Liverpool*, have had considerable success in its application. The efficacy of their preparation is illustrated by a recent case in which the insulation of a steamship, which had been submerged for weeks, on being raised was found intact, not requiring renewal or repair.

The material '*Fosalsil*' (p. 537) is very suitable for insulation purposes.

Insulation on Board Ship.

The insulation of cold chambers on board ship follows the same general principles and method that apply to insulation work carried out on land.

F. 1287

Owing to the way in which the ship's side and deck beams break up the surfaces, and to the absence of pure rectangular spaces, cork slabs are not so simple to use as loose filling materials, but there is, nevertheless, an extending use of cork slabs and an elimination of woodwork, inner linings, and air spaces.

One of the latest methods is the panel system of insulation (Thompson's patents), which, while it is particularly adapted to ships, is also applicable to work on land.

The construction is shown by figs. 8 and 9, and the advantages claimed are:

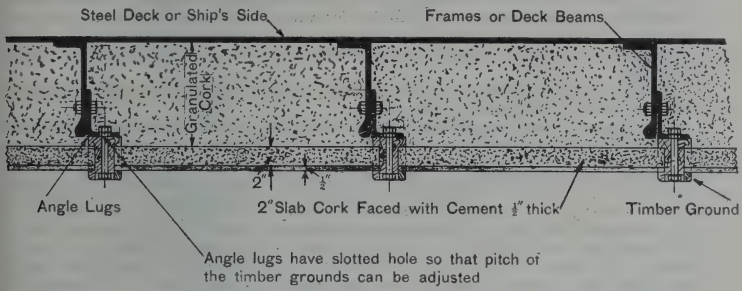

FIG. 9.—Panel System (Thompson's Patent).

(*a*) Any one or more panels can be removed intact without destruction or loss of insulating materials, and can readily be replaced without interfering in any way with the adjacent panel insulation.

(*b*) That the insulation is readily adjustable to the curved surfaces of the ship's plating, and the use of granulated cork, of silicate cotton, or the like, enables the insulation to be thoroughly well packed, no matter how curved or cut up the surface.

(*c*) When cement-faced cork slabs are used, the size of each slab being comparatively small, the liability to surface crack is slight.

(*d*) The wood grounds are exposed on the front faces, their condition can always be examined, and as they are ventilated, the danger of dry rot is greatly reduced.

(*e*) Repairs are easily effected, each panel being separate from all the others.

Operating Refrigerating Machinery.

As refrigerating machinery is solely concerned with temperatures, the gauges connected to the compressor suction and delivery are marked both with a pressure scale and a scale of the equivalent temperatures. The temperature scale should be used for regulating the working of the machine and in making any logs or records, as the differences are then obtained direct without reference to tables of properties.

The gauge on the suction side of the compressor indicates the pressure and temperature of evaporation, and that on the delivery side the pressure and temperature of condensation.

To operate a plant successfully, or analyse its working, it is also necessary to have thermometers to show the temperatures of:

1. The suction gas returning to the compressor from each separate evaporator circuit.
2. The discharge gas leaving the compressor.
3. The liquid refrigerant leaving the condenser.
4. The liquid refrigerant immediately before the regulating valves.
5. The brine leaving the evaporator.
6. The brine returning to the evaporator from each separate brine circuit.
7. The water entering the condenser.
8. The water leaving the condenser.
9. The temperature of the cold storage rooms, or, where a machine is used for special purposes, the temperature of the materials that are cooled.

The first four of these points are frequently omitted in commercial plants, but the second four are essential.

The suction gas thermometer readings should coincide with the evaporator gauge readings unless the suction gas is superheated, and thermometers in this position are particularly useful where there are several separate expansion circuits, as they provide the best indication for the quantity of liquid to be admitted to each, and for the manipulation of the regulating valves.

The discharge gas thermometer readings will be above the condenser gauge readings unless the compressor is run wet compression, and the elevation of the thermometer above the gauge temperature is an index of the dryness of the gas returning to the compressor.

The temperature of the liquid refrigerant will coincide with the condenser gauge reading unless the liquid is sub-cooled either by the use of a counter-current condenser or separate liquid cooler.

Sub-cooling of the liquid, particularly with CO_2, is always an advantage where it is practicable.

The regulation of the quantity of brine flowing through the separate circuits, and consequently of the refrigerating effect, is controlled by the difference between the brine flow and return temperatures.

The quantity of water flowing through the condenser is regulated by the difference in temperature between the inlet and outlet.

It is most important that the machine should be maintained fully charged with its refrigerant, and that supplies should be added from time to time to make good the inevitable small losses that occur with even the most carefully operated plant.

With a proper charge and well-proportioned installation, the condensing temperature should be from 10° to 15° F. above the mean condensing water temperature, and the evaporating temperature from 10° to 15° F. below the mean temperature of the brine, or about 15° to 20° F. below the air temperature when cold storage rooms are cooled by the direct expansion system.

At the same time the suction valve ports on the compressor should be frosted over, and, in the absence of thermometers, the delivery should be as hot as the hand can comfortably bear.

Closing down the regulating valve reduces the evaporating temperature and increases the gas discharge temperature, while opening up the regulating valve increases the evaporating temperature and decreases the discharge gas temperature.

The dryness of the suction gas is indicated by the discharge gas temperature, and while the aim should be to work as nearly as possible dry compression, the conditions of working that best suit individual makes of compressors and proportions of plant can only be determined by experience with them.

An undercharge of refrigerant is indicated by a high delivery temperature, a low condensing gauge temperature, and a low evaporator temperature, which does not rise as it should when the regulating valve is opened.

An overcharge is indicated by a cold delivery temperature, a high condenser gauge temperature, and an evaporator temperature which does not fall at the normal rate when the regulating valve is closed.

Of the two, an undercharge is the more serious, as it results in a reduced refrigerating effect, while an overcharge practically only affects the power required.

The refrigerant should be kept in pure condition by occasionally purging out any air or foreign gases, and the oil separator should be regularly drained to prevent oil passing over into the condenser and evaporator.

Refrigeration on Board Ship.

The use of refrigerating machinery on board ship may be roughly subdivided into three groups:

I. Small plants to cool provision storage rooms and to make small quantities of ice.

II. Large passenger vessels that are arranged to carry refrigerated cargo.

III. Large vessels used primarily for refrigerated cargo.

CO_2 refrigerating machines are almost invariably used for all classes and sizes of machines, and evaporative liquid cooling of the CO_2 is frequently employed.

On steamships the larger machines are practically always steam-driven and incorporate their own steam condensers, but the smaller machines are now generally driven by electric motors, and on motor ships an electric drive is always used.

Compressors running at low and medium speeds are generally preferred, and while direct-coupled sets are sometimes installed, the drive is generally through double helical or other speed-reduction gears.

The third group includes the increasing numbers of vessels used solely for the carriage of tropical fruits, but by far the most valuable and important marine installations are those intended mainly for the carriage of chilled beef.

Some of these have an insulated capacity of upwards of 600,000 cu. ft., and a typical section of such a vessel, together with the arrangement of the refrigerating machinery supplied by *J. & E. Hall, Ltd.*, is shown in figs. 10, 11, and 12.

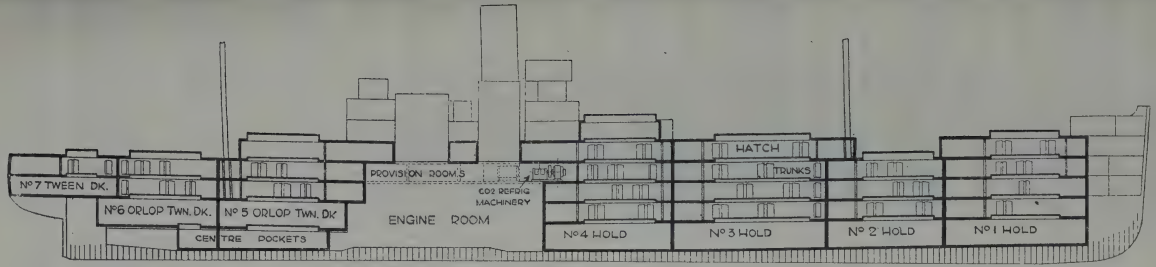

FIG. 10.

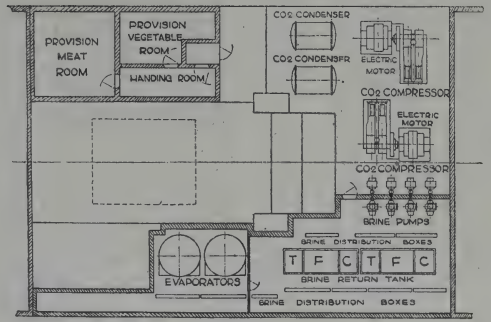

FIG. 11.

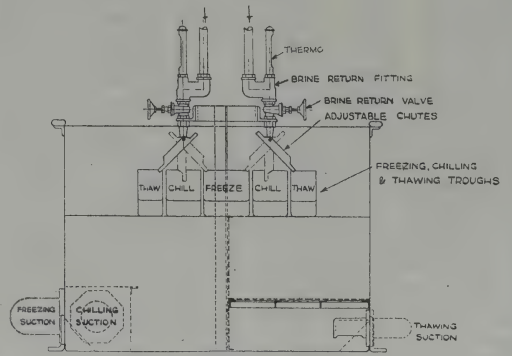

FIG. 12.

In these vessels both chilled and frozen meat can be carried, and the insulated spaces are cooled by piping in them through which cold brine is circulated.

The brine pipes are arranged in a number of circuits of limited length so that the return temperatures shall only show a small rise, and each of these circuits is separately controlled.

In modern practice a number of the spaces are, in many cases, also provided with air-cooling batteries and fans, so that cold air circulation can be used either to supplement the brine piping or as a complete alternative.

The method of cooling by cold air circulation is often preferred for fruit and for other cargoes that are carried at a temperature above the freezing-point.

The carriage of chilled beef calls for very precise regulation of the temperatures to be maintained in the various spaces.

This is effected by what is known as the three-temperature brine system, with mains providing for the delivery of brine at suitable temperatures for freezing, chilling, and thawing service, to enable any temperature from freezing to chilling to be maintained in the various spaces to suit the class of produce carried, and individual requirements of shippers.

The great majority of the large meat-carrying installations are arranged on the open brine circulating system, but the closed system is preferred by several important shipowners.

Both systems have certain advantages; both produce excellent results in practice, and the balance between them may be said to be a matter of individual preference.

The general principle common to both systems is that the brine returning from the piping in the chill spaces is pumped directly back to the chilling delivery header, but the heat absorbed by the brine in its passage through the chilling circuits is eliminated by means of an injection of the freezing brine into the chilling system, there being a corresponding overflow to the freezing system.

When carrying mixed cargoes, it is often an advantage to run one of the evaporators at the chilling and the other at the freezing temperature, instead of having both on the low temperature, and to use the system of brine injection, or attemperating, as it is often termed.

In the open system the brine returns into an open return tank or tanks placed in an insulated space adjoining the machine room, which also contains the headers, valves, cocks, and thermometers required to control the flow of brine.

The arrangement is shown in figs. 11 and 12, and the detailed arrangement of the piping for the same vessel in fig. 13.

An example of the closed brine system is shown diagrammatically in fig. 14, p. 1292, for a vessel fitted up by the *Liverpool Refrigeration Co., Ltd.*

Figs. 15 and 16 (p. 1293) show the form of main attemperating valve and attemperating cock of the Liverpool Refrigeration Co., Ltd.; these, as will be seen, adjust the proportion of chilled or cold brine in such a manner that the one supply is cut off in proportion to the amount the other is opened up.

The flow of brine through the circuits is sometimes controlled by flowmeters placed in them. In other cases no special arrangements are made for measuring quantities, and the control is made entirely on the thermometer readings, but each return has a bye-pass connection, so that the brine may be diverted into an open tank for testing purposes if required.

A large modern installation may involve up to about 200 separate brine circuits, and the control room for a closed brine system fitted up by the *Haslam Foundry & Engineering Company* is shown in fig. 17 (p. 1294).

The refrigerating machinery for these installations always consists of at least two units, each complete with its condenser and evaporator, and capable of independent working, each being of sufficient capacity to maintain the required temperatures in the cargo spaces at sea if the other is out of action.

In some important cases there are three machines, two of which have ample power to maintain the cargo, with one independent unit in reserve.

The machines are often of the Duplex type, with a cross compound engine driving the CO_2 compressors from the tail rods, and arranged so that either side can be used independently. Large single machines are made with tandem compound steam cylinders driving one compressor direct.

There are also a few examples of triple compressor machines with three-cylinder engines, as shown in fig. 18 (p. 1295), illustrating an installation by the *Liverpool Refrigeration Co., Ltd.*

The CO_2 condensers are constructed of solid drawn copper piping contained in cast-iron casings. The evaporators are generally of solid drawn steel piping contained in built steel casings, and in modern practice both brine and water circulating pumps are of the centrifugal type direct coupled to electric motors.

The pump connections to the suction and delivery mains are made to valve boxes, permitting an interchange of duties on the respective chilling and freezing circuits, and for one pump being always available as a standby for either duty.

Water Coolers.

The 'Heenan' Water Cooler.

The latest type of cooler recently introduced by Messrs. Heenan & Froude, Ltd., Worcester, claims a minimum consumption of water per brake horse-power-hour, and has the advantage of being compact and occupying comparatively small space. The apparatus is also self-contained. It is of the stationary type, and has no moving parts beyond the fan which circulates the air, and the pump which circulates the water.

The apparatus (as shown by fig. 19) consists of an outer casing, which is rectangular in shape, built up of mild steel plates. The base of this casing forms a tank into which the water drains after cooling, and previous to re-circulation.

The cooling effect is obtained by evenly distributing the heated water over a number of screens set up one above the other in the body of the cooler.

The water to be cooled, after passing through a strainer, enters at the top of the cooler and falls on to the screens through nozzles which feed perforated troughs. In its fall through the screens it meets a current of cold air which is forced upward through the casing by a centrifugal fan, the discharge from which is introduced to the underside of the lowest screen.

The screens are formed of phosphor-bronze metallic wool of standard size and thickness, held together between brass wire netting which is attached to galvanised angle-steel frames.

The cooling effect is positive and continuous, the cooling surface being always efficient, and the volume of air being a predetermined quantity which is not dependent on climatic conditions. By suitably proportioning the size of the machine for the duty which it has to undertake, water can be cooled down to a temperature closely approaching that of the prevailing wet bulb thermometer. Thus in hot weather—in temperate as well as in tropical climates—re-cooled water can be provided at a temperature considerably below the dry bulb temperature of the surrounding atmosphere. This feature renders the machine especially suitable for dealing with the circulating water of refrigerating plants, for which purpose large numbers of 'Heenan' coolers have been supplied. The practical value of the cooler is due not only to the saving in water but to the improved efficiency of the refrigerating plant, resulting in lower compression pressures and reduced power consumption.

'Pulsometer' Refrigerating Plants.

The Pulsometer Engineering Co., Ltd., are manufacturers of apparatus for working on both the NH_3 (Ammonia), and CO_2 (Carbon Dioxide) compression systems, and their machines are designed and manufactured on the principle that high efficiency as well as reliable and satisfactory service with a minimum amount of attention is of first importance, and apart from the large number of plants of various capacities they supply for land service both in this country and most countries abroad, they are large suppliers of marine type plants for ordinary ships' stores cooling and icemaking, and also for magazine cooling, refrigerating, and icemaking on board war vessels.

A considerable number of cargo and passenger boats have been equipped with this type, and the manufacturers have recently developed an improved design in the form of an enclosed type quick running splash lubrication machine which is particularly suited for both land and marine use. Though marked by many up-to-date improvements, it retains most of the features for which the early designs were so well known, i.e. simplicity and ease of operation with the minimum amount of attention, freedom from breakdown, and low cost of maintenance.

Negretti & Zambra's Low Temperature Electrical Distance Thermometer.

This Thermometer (which depends upon the variation of an electrical resistance by change of temperature) is specially designed for cold-storage work suitable for dairies, butter factories, and meat storage.

The advantage of its installation is that it is possible to read in a central position the temperatures of a number of different points situated some distance away, i.e. the temperatures of cold chambers can be read in the engine room or the manager's office, which is a great advantage and assists the economical working of the plant.

The elements or thermometer bulbs are placed in the cold chambers, brine pipes, etc., and connected up to the indicator by means of lead-covered wire, the electric current being provided by an accumulator. These elements vary according to the purpose for which they are required, either for air temperatures, or for brine or water temperatures.

'HEENAN' COOLER. TYPE 'V.'

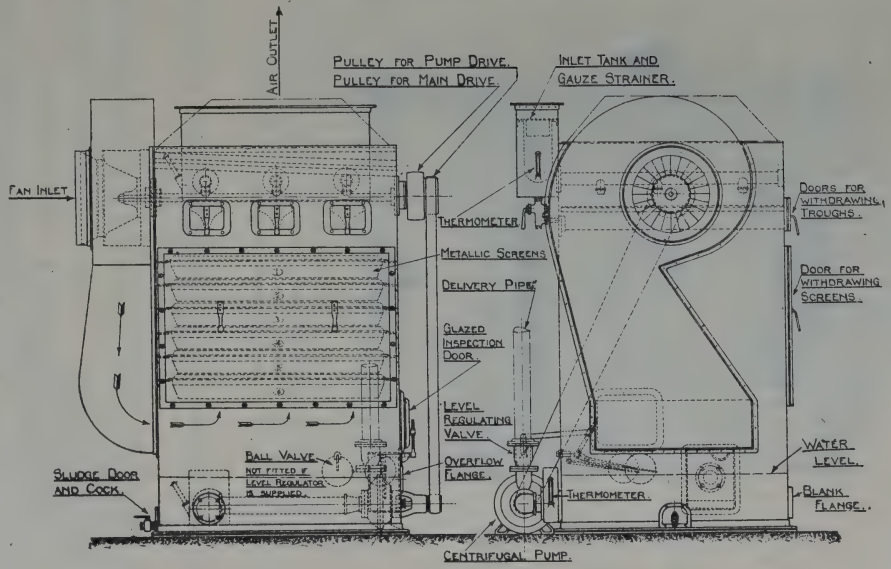

FIG. 19.

The indicator (fig. 20) is mounted in a cast-iron moisture-proof case sprayed and stoved white, the scale being graduated to cover the temperatures required, such as cold stores – 20 to + 100° F., etc. There is a multiple point switchboard incorporated in the case, by means of which the temperature of any point can be read on the indicator as desired.

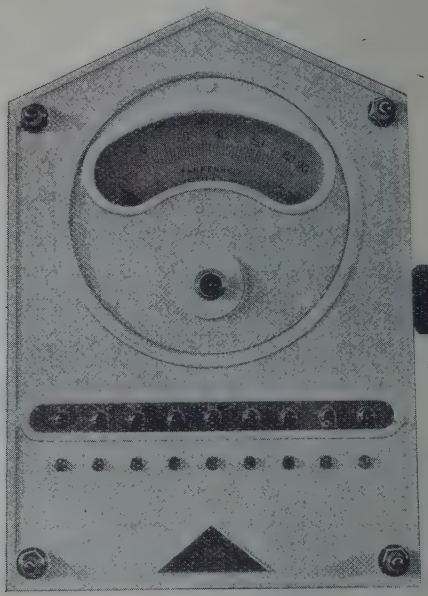

FIG. 20.

All the connections are enclosed in the case, so that they are adequately protected from moisture, dust, etc.

The connecting wire used is a 3-core cable, lead-covered for protection.

LLOYD'S RULES FOR THE SURVEY OF REFRIGERATING MACHINERY AND APPLIANCES OF FROZEN MEAT STORES.

(Abstract.)

Power of Machinery.—The refrigerating machinery is to be of approved construction and of sufficient power to maintain a temperature of 15° F. simultaneously in all insulated chambers when running 18 hours per day.

Motive Power.—Each compressor is to be driven by independent means, or, alternatively, the motive power is to be in duplicate.

Where the compressors are electrically driven, a spare electric generator is to be fitted, unless the power is supplied by a public generating station.

Where electric transformers are installed on the premises, a spare transformer is to be fitted.

Hydraulic and other Tests.—In the case of new refrigerating machinery and appliances, the tests recommended for the various parts are as follows, viz.:

(*a*) CO_2 compressors, separators, condenser and evaporator coils, headers and connections to be tested by hydraulic pressure to 3,000 lbs. per sq. in., and afterwards by air pressure to 1,500 lbs. per sq. in., whilst submerged in water.

(*b*) NH_3 compressors and cast iron or steel connections to be tested by hydraulic pressure to 600 lbs. per sq. in. Where compound compressors are fitted, the low pressure compressor and cast-iron or steel connections to be tested by hydraulic pressure to 200 lbs. per sq. in.

(*c*) NH_3 condenser, evaporator and air cooler coils to be tested by hydraulic pressure to 1,500 lbs. per sq. in., and afterwards by air pressure to 500 lbs. per sq. in., preferably whilst submerged in water.

(*d*) NH_3 plant, after erection in place, to be tested by air pressure; the gas delivery side (*i.e.* from the compressor to the liquid expansion valves) to 200 lbs., and the return side, including the direct expansion piping for the chambers (*i.e.* from the liquid expansion valves to the compressor suction valves) to 150 lbs. per sq. in.

(*e*) Brine piping, after erection in place, to be tested by air or water pressure to 90 lbs. per sq. in.

(*f*) Gas evaporator casings of cast iron and gas condenser casings, whether of cast iron or steel, where of enclosed type, to be tested by hydraulic pressure to 15 lbs. per sq. in., or to double the working pressure, whichever is the greater.

(*g*) Gas evaporator wrought-iron and steel casings, where of enclosed type, to be tested by hydraulic pressure to 30 lbs., if gravitation type, or to 50 lbs. per sq. in. if pressure type, or to double the working pressure, whichever is the greater.

Cooling Tests.—(*a*) Upon completion of the installation under special survey, the refrigerating machinery is to be tested under working conditions, and the insulated chambers are to be cooled down simultaneously to about 15° F.

(*b*) The whole of the refrigerating power may be used in order to reduce the temperature, but the specified temperature is to be maintained in the insulated chambers for a period of 12 hours with the spare compressor unit out of action.

Brine Cooling System.—(*a*) Where the brine system of refrigeration is employed the cooling pipes in each refrigerated chamber of over 5,000 cu. ft. capacity are to be arranged in not less than two sections, and the cooling surface is to be sufficient to maintain the working temperature of the chamber when one of the sections is out of use. Isolating valves or cocks are to be fitted to each section of cooling pipes.

(*b*) The brine circulating pipes and brine tanks should not be galvanised on the inside.

(*c*) In cases where internally galvanised tanks or cooling pipes are fitted, the brine cooling and return tanks, if of closed type, are each to be provided with a ventilating pipe or pipes led to the open air in a situation where no danger will be incurred from the issuing gas, and each ventilating pipe is to be fitted with a wire gauze diaphragm which can easily be removed for renewal.

(*d*) Where the tanks are not closed the compartments in which they are situated are to be efficiently ventilated.

Direct Expansion System.—Where the direct expansion system of refrigeration is employed, the cooling pipes in each refrigerated chamber of over 5,000 cu. ft. capacity are to be arranged in not less than two sections, and the cooling surface is to be sufficient to maintain the working temperature of the chamber when one of the sections is out of use. An expansion valve and a return gas valve or cock are to be fitted to each section of cooling pipes.

General Data Regarding Water.

An imperial gallon of water at 62° F. weighs 10 lbs. avoirdupois. (See also page 236.)

Gallons × 277·420 = cu. ins. (*International Bureau of Standards, Paris*, 1921.)

Gallons × 0·16055 = cu. ft.
Cu. ft. × 6·2288 = gallons.
Cu. in. × 0·0036047 = gallons.
Cu. ft. × 62·288 = lbs. weight.
Lbs. × 0·016053 = cu. ft.

Gallons × 0·004464 = tons.
Tons × 224 = gallons.
Cu. ft. × 0·027807 = tons.
Tons × 35·962 = cu. ft.

A pipe one yard long holds approximately (actually, 1·52 per cent. less) as many lbs. of water as the square of its diameter in inches; thus, a 6-inch pipe holds approximately 36 lbs. of water in each yard length.

VISCOSITY (ν)* OF WATER IN C.G.S. UNITS AT VARIOUS TEMPERATURES.

(Calculated from data in *The Philosophical Transactions of the Royal Society*, A., Vol. 214.—*H. R. K.*)

C.°	8·6	10·2	10·5	10·7	11·1	11·3	11·5	14·3	15·0	16·0	20·5	23·0	25·0
F.°	47·5	50·4	50·9	51·3	51·9	52·3	52·7	57·7	59·0	60·8	68·9	73·4	77·0
ν	0·0136	0·0131	0·0130	0·0129	0·0128	0·0127	0·0126	0·0115	0·0114	0·0110	0·0100	0·0093	0·0090

Approximately the viscosity at 69° F. is 0·01. The viscosity varies approximately 2·06 per cent. for each C.°, or 1·2 per cent. for each F.°

Water-Pressure.

If

H = head of water in feet; P = lbs. pressure per square inch,

$H = P \times 2{\cdot}311$. $P = H \times {\cdot}4326$.

10 feet head of water gives a pressure of 4½ lbs. per square inch, approximately,

27·71 inches of water gives a pressure of 1 lb. per square inch.

* See note p. 1072.

(*H. R. Kempe.*)

Horse-power required to Pump Water.

1 H.P. indicated will raise about 3,000 gallons of water per hour 50 feet high.

To pump 1 gallon of water per minute against a pressure of p lbs. per square inch requires $p \times \cdot0007$ H.P.

Allowing 40 per cent. for friction, the following shows the H.P. required to pump 1 gallon of water per minute at various pressures :—

Pressure per square inch, in lbs.	500	700	1000	1200	1500	2000	2250	2500	5000
Horse-power	·49	·69	·98	1·18	1·47	1·96	2·21	2·45	4·90

The *cost of lifting* 1 ton 50 feet is, in the case of the London Hydraulic Power Company, sometimes as low as $\frac{1}{4}d$.

Speed of Water should not, as a rule, exceed 100 feet per minute with 700 lbs. pressure. In the mains of the London Hydraulic Power Company the delivery is 1,040 gallons per minute, at a velocity averaging 2·83 feet per second, or 170 feet per minute. The loss of head due to this velocity is 22·896 feet per 1,000 yards, by the formula :—

$$\frac{(\text{Gallons per minute})^2 \times (\text{length of pipe in yards})}{(3 \times \text{diameter of pipe in inches})^5}$$

The most distant point of the main is 5,320 yards, or just over 3 miles, from the accumulators. In a circuit of 5 miles the normal difference of pressure, or loss of head, was 20 feet head.

Pressure in Hydraulic Mains.

The average working pressure is 700 lbs. per square inch with accumulators, but varies from 300 to 1,500 lbs. per square inch. The pressure in the mains of the London Hydraulic Power Company averages 700 lbs., the actual pressure at the accumulators being 750 lbs.

700 lbs. per square inch = 549·78 lbs. per circular inch, equivalent to a head of 1,618 feet.

EFFECTIVE PRESSURE WITH 700 LBS. AT ACCUMULATOR.

Dimensions of Hydraulic Pipes and Cylinders.

TABLE OF THICKNESS OF HYDRAULIC PIPES.

Description.	Wrought Iron, to stand 4,000 Lbs. per Square Inch.										Cast Iron, to stand 700 Lbs. per Square Inch.						
Internal diameter, in inches	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{4}$	$1\frac{1}{2}$	$1\frac{3}{4}$	$1\frac{5}{8}$	$1\frac{1}{2}$	$1\frac{5}{8}$	2	$2\frac{1}{2}$	$2\frac{1}{2}$	3	3
External diameter in inches	$\frac{3}{4}$	1	$1\frac{1}{4}$	$1\frac{1}{2}$	$1\frac{3}{4}$	$1\frac{1}{2}$	$1\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{7}{8}$	$2\frac{1}{8}$	$2\frac{3}{4}$	$2\frac{3}{4}$	$3\frac{1}{4}$	$3\frac{9}{16}$	$3\frac{15}{16}$	$4\frac{3}{4}$	$5\frac{1}{4}$
Number of threads per inch	14	14	14	11	11	11	11	11	11	11							

(1)

The external diameter, D, may be calculated from the formula :—

$$D = d\left(\frac{p}{f} + 1\right),$$

where,

d = diameter of bore of pipe, in inches ; p = pressure, in lbs., per square inch ; f = 4,000 for wrought iron, and 1,200 for cast iron.

(2)

$$T = \frac{(P + 100)\,D}{0{\cdot}4\,S} + 0{\cdot}333\left(1 - \frac{D}{100}\right),$$

where,

T = thickness of pipe in ins.; D = interior diameter of pipe in ins.; P = pressure of water in lbs. per sq. in.; S = ultimate tensile strength of cast-iron in lbs. per sq. in. (taken as 18,000 lbs.).

This formula gives the weight and thickness for good, tough, and elastic cast-iron pipes covering the ordinary range of static pressures of public water supplies.

60	1·35	1·50	1·70	—	—

(*R. D. Wood & Co., America.*)

(3)

$$T = \frac{(P + L)\,R}{3{,}300} + 0{\cdot}25.$$

where

T = thickness of pipe in ins.; P = static pressure in lbs. per sq. in.; R = inside radius of pipe in ins.; L = pressure in lbs. allowed for water hammer; 0·25 = a constant allowance for inequality in manufacture, deterioration, and rough handling; 3,300 = one-fifth of the tensile strength of cast-iron, which is taken to be 16,500.

The values of L—the allowance for water hammer—for different sizes of pipe are as follows, the allowance decreasing as the diameter and thickness of pipe increase :—

Diameter of Pipe, Ins.	Value of 'L,' Lbs.	Corresponding Head, Ft.
3, 4, 6, 8, or 10	120	277
12 or 14	110	254
16 or 18	100	231
20	90	208
24	85	196
30	80	185
36	75	173
42, 48, 54 or 60	70	162

For a static pressure of 100 lbs. per sq. in. a 6 in. pipe need be only 0·10 in. thick. Such thin pipe, however, could not well be made or handled, and allowance must be made (as above) for shock due to water hammer, for roughness in handling, for inequality in manufacture, and for deterioration. (*D. Fitzgerald, America.*)

Thickness of Hydraulic Cylinders.

If T = thickness of metal in inches, P = bursting pressure in lbs. per square inch, R = radius of cylinder in inches, and C = constant (16,000 for cast iron, 34,000 for brass, 50,000 for wrought iron, and 70,000 for steel),

$$T = \frac{PR}{C - P}.$$

If D = external diameter of cylinder in inches, and d = internal diameter in inches, P and C being as above, then

$$D = d\sqrt{\frac{C + P}{C - P}}.$$

Strength of Hydraulic Cylinders.

If f = allowable stress in lbs. per sq. in.; P = working pressure in lbs. per sq. in.; d = inside diameter in ins.; D = outside diameter in ins.; then

$$D = d \times \text{anti-log}\left(\frac{P}{p} \cdot 4343\right). \qquad (Clark.)$$

EXAMPLE.—If P = 3,000 lbs. per sq. in.; f = 8,000 lbs. per sq. in.; d = 30 ins.; then

$$\frac{P}{p} \cdot 4343 = \frac{3{,}000}{8{,}000} \cdot 4343 = \cdot 16286$$

anti-log.* of $\cdot 16286 = 1 \cdot 455$ (page 99);

therefore $D = 30 \times 1 \cdot 455 = 43 \cdot 65$ ins.

Size of Hydraulic Mains.

The largest mains used for hydraulic purposes are 7½ inches in diameter. The working stress on the metal due to working pressure is 2,800 lbs. per square inch. The mains are usually tested to a water-pressure of 2,500 lbs. per square inch before laying, and to a pressure of 800 to 1,600 lbs. per square inch after laying.

Pipe Unions and Joints.

For wrought-iron pipes up to 2 inches in diameter, such as are used for the connecting-pipes to hydraulic machines, the unions are generally of brass, and of the form shown by fig. 1. For

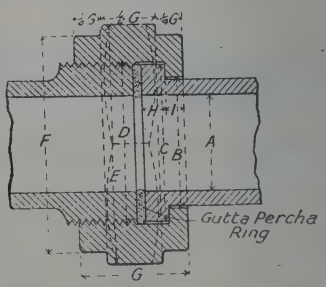

FIG. 1.

main cast-iron pipes the unions are made by means of elliptical flanges (fig. 1) formed on the ends of the pipes, the inner faces of the flanges being turned so that one pipe can enter a little distance into the other; a recess is left between them, to receive a gutta-percha ring, whose outside diameter is about 4 times the inner.

---

Mains fitted with flanged joints of the description shown by fig. 2 can be made absolutely tight and free from leakage. The flanges are placed in a horizontal position in laying.

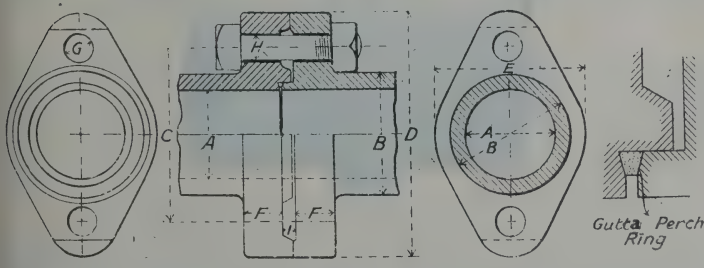

FIG. 2.

Mr. Ellington (engineer of the London Hydraulic Company) found that fractures in the pipes occurred by the breaking off of one of the bolt lugs. By placing the lugs a little farther back on the pipe the strength was found to be greater. It is probable that the slight flexibility of the pipe line which this kind of joint allows is an important element in its success.

On low-pressure hydraulic systems ordinary socket joints can be used.

In the *Philosophical Magazine* the Earl of Berkeley and Dr. Burton have described a simple form of joint packing, which is, they state, tight to start with and maintains this tightness up to the highest pressures they have employed, which have attained 1,500 atmospheres, or

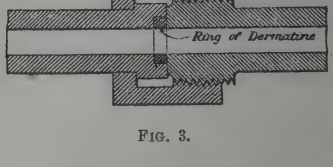

FIG. 3.

say, 10 tons per square inch. The pipe ends (fig. 3) are faced, and a recess is cut in one to take a ring of dermatine; this ring must be slightly thicker than the depth of the recess so that it is slightly compressed when the joint is tightened up. Either red or black dermatine may be used, but the red, being harder, is more easily machined. The joint is said to be equally good for water or oil, and is as suitable for a flanged joint as for a screwed coupling. It is also said to be as satisfactory with large pipes as with small.

THE 'VICTAULIC' SYSTEM OF FLEXIBLE PIPE LINES.

This system (fig. 4) employs pipes with shouldered ends, which are engaged with a certain amount of clearance by the split housing of the joint, which, while coupling the pipes together, permits disalignment or movement due to expansion of the pipes.

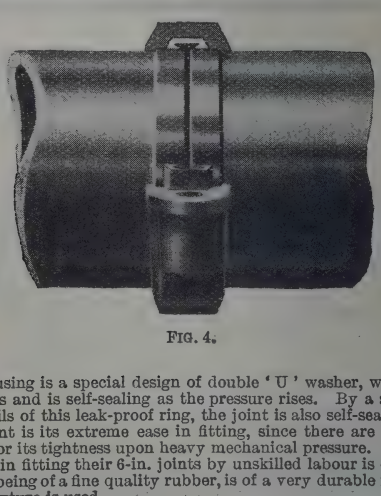

FIG. 4.

Within the split housing is a special design of double 'U' washer, which exercises an initial grip upon the pipe ends and is self-sealing as the pressure rises. By a special proportioning of the buttress-shaped walls of this leak-proof ring, the joint is also self-sealing against a vacuum.

A feature of the joint is its extreme ease in fitting, since there are only two bolts and the joint is not dependent for its tightness upon heavy mechanical pressure. The makers claim that the average time taken in fitting their 6-in. joints by unskilled labour is only two minutes.

The leak-proof ring, being of a fine quality rubber, is of a very durable nature; for oil or gases, acids, etc., a special mixture is used.

The joint is not supplied for use with steam.

Fittings, valves, etc., are all supplied with the ends shouldered or expanded in the same way as the pipe ends, and complete installations can be rapidly built up.

The dimensions of pipe ends are standardised by all the leading tube makers (see table on page 1235), so that all joints and tubes of the same nominal bore will match up together.

Cement Joints for Cast-Iron Water Mains.

(1.)

The pipe is placed and spaced in the usual manner. A thin backing of the best dry jute is used instead of oakum, as the jute is free from oil and grease, which should be avoided. Portland cement is placed dry on a piece of canvas (usually a cement sack ripped open) and moistened so that when thoroughly mixed by hand it will be of such a consistency that when gripped tight it will take the form of the hand and when dropped 12 ins. will crumble. The canvas containing the cement is placed under the bell, and the cement tamped into place by hand with a caulking iron until the bell is about half full. It is then caulked with heavy blows until the cement is thoroughly packed in the back of the socket. The process is continued until the bell is packed solid out to the face. A small bead of neat cement is then put on (this is essential), the caulking iron being used as a trowel, and, as soon as the initial set of the cement in the bead has taken place, the joint is covered with earth to protect it from the air and sun. In back-filling the excavated material is always settled with water, which helps to cure the exposed portion of the joint. The joint is allowed to stand forty-eight hours before the pressure is turned on and the main put into service. At Long Beach, California, there are now sixty miles of cast-iron water mains, ranging from 4 ins. to 24 ins. in diameter, laid with joints of this type. All these pipes are under pressures ranging from 40 lbs. to 80 lbs. per sq. in., and are giving satisfaction.

(*Clark H. Shaw, the American Society of Civil Engineers.*)

(2.)

A method of cement jointing cast-iron water pipes is described by Mr. G. W. Pracy in the *Journal of the American Waterworks Association*. The spigot end of the pipe projects into the bell just the same as for a lead joint, and two rings of jute or yarn are placed round the pipe and driven into the bell in the regular manner. The jute used must be free from oil or tar. Neat cement of standard Portland cement brand is used. The mix is very dry, the proportions being about 13 lbs. to 14 lbs. of cement to 1 lb. of water. The operator takes a handful of cement, and with an ordinary caulking iron forces the cement into the joint until full. He then takes a caulking hammer and caulks the joint until the cement is rammed in as hard as possible. The joint is then again filled and the operation repeated until the joint is completely filled with the rammed cement. At first a bead was put around outside the bell, but this was discontinued as being unnecessary. After the joint is finished it is covered with earth while the cement is hardening. In one case over a mile of piping jointed in this manner has been in use under 175 lbs. per square inch pressure for more than two years without requiring any repairs. It is claimed the method is cheaper than lead joints, and one indirect advantage is that the cement joint is an insulating joint, which tends to reduce damage from electrolytic action.

Pipe Joints for Petrol.

Pipe joints for petrol at ordinary atmospheric temperatures can be made up tight by first filling between the screw threads of the pipe with a thin paste made of gum shellac dissolved in a 10 per cent. solution of ammonia. The screw threads of both pipe and fittings should be thoroughly cleaned of grease before application of the paste.

Concrete-Lined Metal Pipes.

It has been American practice for some years past to line metal pipes with a thin coating of cement, which usually does not exceed three-eighths of an inch in thickness, applied by brush, cement gun, or by hand tamping. The experience gained with such pipes, some of which have now been in continuous service over periods of eight to ten years, showed that no appreciable incrustation had taken place even with bad waters. The iron or steel pipe lined with cement was found to have the further advantage that the interior surface could be rendered perfectly smooth—making its coefficient of friction not appreciably different from that of a new cast-iron pipe.

Stanton Centrifugally Concrete-Lined Pipes.

A rotary motion is imparted to the pipe by four friction wheels driven by chains and operated by a hand-controlled variable-speed motor. The pipe having been trued up, internal rings are placed in position in order to prevent the concrete coming out at the ends of the pipe during the spinning process. During the first spin the pipe is rotated slowly over a period of about ten minutes, during which time the sand and cement concrete is shovelled into each end of the pipe by hand. Owing to the centrifugal force the cement does not fall down, but adheres to the surface of the pipe, and further consolidation is effected by passing a 3-in. diameter rod with a bronze sleeve through the pipe and pressing this by hand against the revolving internal surface. After the correct thickness has been deposited the pipe is spun at a higher speed, which drives the coarser particles of the concrete towards the iron surface of the pipe and gradually expels the water and slurry from the internal surface. During the spin the water and slurry form a thin revolving film, which, as soon as the pipe is brought to rest, falls to the bottom of the pipe. The internal end rings are then removed and the water brushed out. The concrete lining is now quite hard, and after three or four weeks in the open the pipe is ready for service. In the larger pipes the lining is about $\frac{1}{2}$ in. in thickness, but it may be increased up to 1 in. or more if so desired.

Pipes from 4 ins. to 72 ins. diameter may be lined.

The concrete lining is so finished at the socket end that when the joint is made the water in the pipe is only in contact with concrete and does not touch the iron in any part.

A pipe may be drilled and tapped without the concrete unduly breaking away at the edges of the hole, while the operation of running and caulking the joint can be carried out without detrimental effect on the lining. The effect of exposure to the weather has been investigated by leaving a 48-in. diameter pipe in the open for two years, and although subjected to effect of sun and frost no alteration has been detected either in the metal or in the concrete. A modified form of construction is represented by a series of 60-in. diameter pipes made for the Birmingham Corporation. The shells of these pipes are made from $\frac{3}{8}$-in. steel plates bent and welded into a 5-ft. diameter circle. The steel tube is so light that when the finished shell is placed on the ground it takes up a more or less oval form, being distorted in diameter by nearly $\frac{1}{2}$ in. These tubes are filled with a concrete lining $1\frac{1}{4}$ in. in thickness, which, when formed by spinning, is sufficiently strong to prevent all distortion and give to the pipe a perfectly round shape.

The process of centrifugal lining has also been most successfully applied to the new spun cast-iron pipes which are being manufactured at Stanton in sizes from 4 ins. up to 15 ins. in diameter. The spun cast-iron pipe has not only the advantage that it is nearly 25 per cent. lighter than the ordinary vertical sand-cast pipe, but the way in which it is made ensures a perfectly round and true pipe, avoiding the necessity of re-truing before the lining process.

SECTION XXV

PART II

PUMPS — STEAM PUMPS — PUMP PACKING — CENTRIFUGAL PUMPS—TURBINE PUMPS—AIR LIFT PUMPS.

PUMPS.

The surface of the water to be raised should not be more than 25 feet below the movable valve.

Especially for small pumps, the suction pipe of a pump should fall all the way from the pump to the supply well. Any upward bend in the suction pipe introduces an air trap and may seriously diminish the performance of the pump.

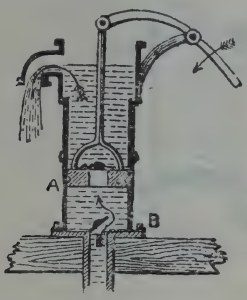

Fig. 1.

Fig 2.

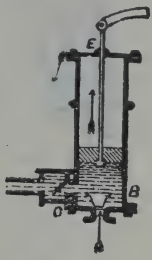

Fig. 3.

The Suction Pump.

This form of pump, which is shown by fig. 1. consists of a cylinder, called 'the barrel,' with valve, B, in which works a piston, A, called 'the box,' with valve in it, both valves opening upwards. The piston is attached to a rod and worked by a handle. When the handle is raised the piston is depressed: the valve A opens upwards, allowing the water or air below it to escape into upper part of cylinder. When the piston is raised the valve in it is closed, the water above is lifted up through the spout, the water from below lifts the valve at B, and rushes up to fill the vacuum caused by the raising of the piston.

If the valves are very dry a little oil should be poured on them. A little water poured on the piston before commencing to work it, makes it air-tight.

Lifting Pump.

The suction pump is converted into a lifting pump by attaching a pipe in place of a spout at C (fig. 2), with a valve in it, opening upwards to prevent the return of the water. A stuffing-box is provided for the piston-rod to work in at E. Each time the piston, A, is raised the water above it is forced up the pipe, and, as the piston descends, the valve C prevents the return of the water from above. It is clear that the man who pumps must exert at each upward stroke of the piston as much strength as is necessary not only to raise a cylinder full from below, but also to lift the column of water in the pipe above.

The valve C is not necessary to the action of the pump, because, the barrel being full, the valve B retains all the water. It is used more as an additional check. The pump would also act if only valve C were in and B removed.

Single-acting Force Pump.

This form of pump, shown by fig. 3, is used to force up water to a height. The piston is made without a valve. The delivery pipe is at bottom of piston: it has a valve opening upwards at C to prevent the return of the water. When the piston is raised the valve B opens and the water rushes into the cylinder: when the piston descends valve B closes, valve C opens, and the water is forced up the pipe. In this pump the force is required for the down stroke. The top of the cylinder E need not be closed; a little water poured in above the piston makes it air-tight.

Plunger Pump.

Sometimes a solid plunger, A (fig. 4), is substituted for the piston, to avoid the expense of turning the cylinder true, and also because it resists better the wear from grease and dirt. At each stroke it raises a volume of water equal to that of the plunger.

Double-acting Force Pump.

This pump (fig. 5) sends up water both at the up and down stroke. At the up stroke the water above the piston is forced through the valve A, while that below enters the piston at the valve D; at the down stroke the water is forced through the valve C, whilst it enters above the piston at the valve B.

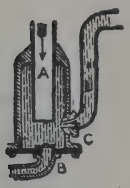

Fig. 4.

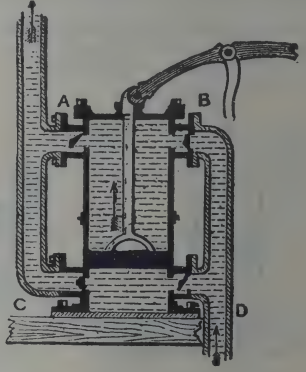

Fig. 5.

In all force pumps the packing of the piston or box is of great importance; it is commonly made of waste tow soaked in tallow and rammed tight; or for great pressures, cup leather packings are used.

Working Barrels, Buckets, and Valves.

These should be made of brass, gun-metal, or phosphor bronze, which metals, although costly in the first instance, will be found more durable, to require less repair, and to be more accurate in their operation than iron, being much less liable to injure the leather attached to the bucket and valve, the parts most frequently in want of repair.

An alloy which will withstand the action of water under pressure in a metal valve, and which is used by one of the largest firms in the country, consists of the following ingredients:—Copper, 10; tin, 1; zinc, $\frac{1}{16}$; lead, $\frac{1}{8}$.

The suction-pipe should be two-thirds the diameter of working barrel.

Pump Balancing.

To ensure equal work on the up and down strokes of a pump, it must be balanced. A complete balance provides for the whole weight of metal hung on the crank pin or beam, and one half the water work. The case of a bucket and plunger pump is perhaps the least simple, as in a bore-hole pump with a plunger at the surface delivering to a height above the surface.

Let A = area of bucket; a = area of plunger; W = weight of moving parts hung on crank pin and immersed in air; w = ditto immersed in water, e.g. the bucket and rods; H = height from water-level when pumping to plunger, in feet; h = height from plunger to point of delivery, in feet; B = balance weight to act at same lever arm as crank pin; then

$$B = W + 0{\cdot}875\, w + 0{\cdot}216 \left\{ [A \times H] + [(A - a) \times h] - [a \times h] \right\}.$$

The coefficient 0·216 represents one half the work, and the relation of pressure to head, or $0{\cdot}5 \times 0{\cdot}43$.

The correction for the different specific gravity of a gun-metal bucket may be neglected. Modern rods ultimately become as heavy as water, but at first have some negative weight. If a balance weight moves through a greater range than the cross-head, it must be correspondingly reduced.

Pumping from Wells.

For wells under 30 feet a 4-inch working barrel with a 9-inch or 10-inch stroke should be used. This size pump will throw 24 gallons per minute from a 20-feet well, and is as large as one man can conveniently work, and the best adapted for general use. For wells above 30 feet and under 70 feet a 3½-inch working barrel with a 9-inch or 10-inch stroke. For wells above 70 feet deep three 3-inch barrels, worked with a three-throw crank wheel and pinion in cast-iron case with fly-wheel, etc.

Artesian Well Pumps.

When the water level in a bore-hole is far below the surface, say 25 to 300 or 400 ft., it is necessary to place the pump barrel down the bore-hole, and it is usually desirable that it shall be lower than the rest level of the water, so as to be charged for starting work.

A bore-hole pump consists of a barrel of gun-metal with a bore at least 1 in. to 1¼ in. less than the diameter of the well lining tube. The barrel is screwed upon a rising main, which must be at least ⅛ in. to ¼ in. bigger than the barrel. The pump bucket and lower valve can thus be drawn up through the rising main for repair or inspection. A 4-in. pump will have a stroke of 1 to 3 ft. as desired, and a speed of 15 to 30 up strokes per minute. For durability it is desirable with very deep pumps to run at slow speeds. The pump rod terminates in a gun-metal rod or plunger, which passes through a stuffing box in the casting which forms the head of the pump. This head is flanged to the lining tube and screwed upon the rising main, and a branch is cast on one side for the water. If the lift above surface is considerable, it is possible partially or wholly to balance the lift of water to the surface by the use of a plunger, which may, if required, be as large in diameter as the bucket. However arranged, in order to equalise the work on the up and down strokes, it is proper to balance half the water lifting, and all the weight hung on the crank pin, so that the duty of the motive power may be evenly distributed in up and down strokes. Comparatively short pumps can be balanced by a weight in the main spur wheel on the crank shaft. When deeper, this is not sufficient, and a weighted lever may be linked to the crosshead pin and fitted with a balance weight on its outer or long end.

Some makers hang a heavy weight upon a pin in the face of the spur wheel, other makers attach wire ropes to the pump crosshead and pass them over a wheel and hang a weight, in guides, upon the ropes. Some engineers prefer to employ wooden pump rods, on account of their large displacement, so as to reduce the balance weights necessary.

A deep-well pump, unless small and slowly driven by a windmill, should be two to three diameters in length, of plain cylindrical form, with alternate grooves, with square-cut corners, and plain body. The grooves should be ¼ in. × $\frac{1}{16}$ in. and the space between, $\frac{5}{16}$ in., the two extreme spaces about ⅝ in. to ¾ in. No rings or packing leathers should be used.

The bucket valve may be mushroom, ball, or flat dermatine, the foot valve the same, in a taper casing, or foot piece which fits in the taper foot piece of the barrel. Under the bucket is a female screw which fits upon the thread projecting above the guard of the lower valve. When it is desired to remove the foot valve for inspection, it is lifted out by the bucket and pump rods, the bucket being lowered upon the valve and screwed to it; the valve then comes up with the bucket.

These pumps are usually driven from a second motion shaft by wheel and pinion, the second motion shaft carrying a fast and loose pulley driven by a belt from the engine or main shaft.

In country house work an oil-engine or an electric motor may be the driving agent, speed being reduced by more pairs of wheels or by larger driven wheels and pulleys. Or an electric motor may be worm-geared to the crank-shaft direct, in which case it is sometimes desirable to interpolate a friction clutch, so that the motor can be started off the load. Larger plants, such as the pumps for small town supplies, are perhaps best driven by gas-engines and suction gas plants.

Steel worms working in phosphor bronze wheels are said to give the best results. The wheel should be hollow faced so as partially to embrace the worm, and the angle of the teeth across the face of the wheel should be about 45°, so that the worm may require to be double or treble threaded to secure this. A thrust collar, or rather several collars, of propeller thrust type, are required on the worm shaft; but it is probably better to employ two worms, right and left, and two wheels connected to the same work, so that the thrusts balance, and no thrust block is required. The wheel should run in oil, which should be not too viscous. If a thrust block is employed, it should not be enclosed too narrowly, especially if near to the worm, as this has been found to prevent free access of oil.

When the water level in a bore-hole is not too deep below the surface, the air lift pump may be used with advantage, but it falls off in efficiency at great depths, and may often necessitate the boring of the well to depths very much greater than would be necessary merely to give the water yield. (*See also* Air Lift Pump, p. 1339.)

Discharge from Reciprocating Pumps.

TABLE OF CONSTANTS WHICH, MULTIPLIED BY EFFECTIVE NUMBER OF STROKES PER MINUTE, GIVE THE DISCHARGE IN GALLONS PER HOUR.

CAPACITY OF PUMP.

If

d = diameter of barrel, in inches; s = stroke, in inches; n = number of acting strokes per minute; g = gallons per hour; then

$$g = d^2sn \div 6, \text{ approximately.}$$

Semi-Rotary Pumps.

THE WILLCOX SEMI-ROTARY WING PUMP.

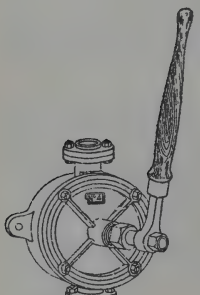

FIG. 6.

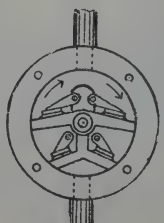

FIG. 7.

These pumps, figs. 6 and 7 (*W. H. Willcox & Co. Ltd.*), are made either double (as shown in the figs.) or quadruple acting. The working parts are of metal, and the wear and tear is reduced to a minimum; they are claimed to be lighter and occupy less space than any other pumps of equal capacity, and are self-contained. Although fig. 6 shows a form for hand-working, these pumps are adapted for being fitted to any kind of motive power and can be employed for all general purposes.

PARTICULARS OF WILLCOX SEMI-ROTARY PUMPS.

No. of Size.	Approximate Capacity per hour, and Price.						Size of Suction and Delivery Pipes (inside).
	Double Acting.			Quadruple Acting.			
	Galls.	Cast Iron.	Brass.	Galls.	Cast Iron.	Brass.	Ins.
0	270	£1 16 0	£2 10 0	360	£1 18 0	£2 12 0	¼
1	420	2 0 0	2 16 0	480	2 4 0	3 0 0	¾
2	540	2 8 0	3 12 0	660	2 10 0	3 16 0	1
3	660	2 18 0	4 13 0	960	3 4 0	4 16 0	1¼
4	900	3 12 0	5 11 0	1,260	3 18 0	6 0 0	1½
5	1,200	4 0 0	6 19 0	1,440	4 10 0	7 4 0	1½
6	1,500	4 16 0	8 7 0	1,740	5 10 0	8 16 0	1½
7	1,860	6 4 0	10 4 0	2,160	6 16 0	11 2 0	2
8	2,460	8 0 0	14 16 0	2,700	9 0 0	15 15 0	2
9	3,300	11 0 0	17 15 0	3,840	11 16 0	18 10 0	2½
10	3,720	15 4 0	24 1 0	4,980	15 16 0	25 0 0	3
11	4,320	18 2 0	29 12 0	6,000	19 0 0	31 10 0	3
12	—	—	—	8,280	38 0 0	69 5 0	4

The capacities in the foregoing table are based on 3 ft. suction, 3 ft. delivery, and on a full stroke; but the pumps will lift 25 ft. and force to a height of about 70 ft., according to size and speed.

Willcox Semi-Rotary Wing Pumps can be supplied with rubber balls for thick liquids, etc., and with phosphor bronze balls for acids, etc.

THE BOULTON WATER ELEVATOR.

This water elevator consists of an endless band to which are fixed a series of open-ended cells, so designed as to retain water by surface tension. The band is shown in fig. 8 and the general arrangement of the apparatus in fig. 8A.

FIG. 8.

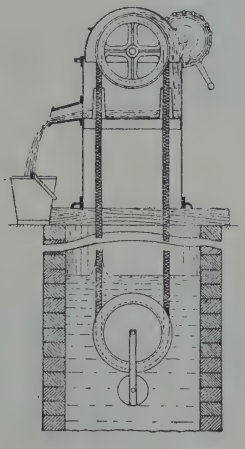

FIG. 8A.

The band passes over a driving pulley at the top, carried in a suitable casing. At the lower end a weighted pulley is carried in the loop formed by the band and is submerged in the water.

When the top pulley is rotated the band is set in motion, carrying on the upward side water which is released in passing over the top pulley by centrifugal force breaking down the surface tension.

The bands are made in various sizes, both single and multi-element, ranging in output for power operation from 284 to 19,500 gals. per hour. For hand use outputs of 2·8 gals. per minute from 220 ft. deep, or 13 gals. per minute from 50 feet, can be obtained by one man.

The Boulton water elevator is suitable for dug wells of practically any depth; installations as deep as 410 ft. having already been successfully undertaken.

The efficiency is very high. From official independent test figures a band efficiency of over 95 per cent. on a well 150 ft. deep was recorded.

The headgears are made in various types to suit most purposes, both with and without force pumps, for delivering to heads above the elevator.

The elevator can also be used for handling sewage, sludge, etc., and the band and elements are practically non-corrodible.

On wells over about 30 ft. the cost is very much lower than ordinary deep-well pumps, and amongst its chief advantages are (1) ease of installation, there being no need to descend, and nothing to fix in the well; (2) simplicity—no valves, buckets, plungers, or pipes in the well; (3) it is unaffected by frost; (4) high efficiency; (5) suitable for wells where there is a big variation in water level; (6) the band is not an articulated construction, and has no pins or knuckles to wear or corrode.

STEAM PUMPS.

The Clarke, Chapman Direct-Acting Feed Pumps.

(*Woodeson's Patent.*)

The single-cylinder direct-acting type of pump, on account of the small number of working parts and consequent small liability to break down, is very largely employed. Figs. 9 and 10, p. 1319, show Woodeson's 'Simple' Patent Direct-acting Pump (*Clarke, Chapman & Co. Ltd., Gateshead-on-Tyne*). This pump, which is extensively used, works with all steam pressures up to 400 lbs. per sq. in.

The steam chest is manufactured of the best hard close-grained cast-iron, of a suitable thickness to withstand any tendency to distort through the temperature of high-pressure steam.

The working parts of the steam chest consist of one auxiliary valve and one main valve, both of piston valve type.

The auxiliary valve is operated by the valve gear, actuated by the piston-rod crosshead. The main valve is partly moved mechanically and partly operated by steam, controlled by the auxiliary valve.

The action of the valves is as follows:—

When the main piston is nearing the end of its stroke, and the auxiliary valve commences to be moved by the valve gear, the first part of the movement closes the port through which the exhaust from one end of the main valve has been passing. The next part of the movement of the auxiliary valve opens steam to this end of the valve, and as the steam to the opposite end has not been closed, the main valve is in equilibrium. By the time that this takes place the auxiliary valve has moved so as to be in contact with the main valve, and further movement of the valve gear causes the auxiliary valve to move the main valve mechanically and so close the ports to the main cylinder. When these ports are nearly closed the auxiliary valve has closed the steam port at the end of the main valve, towards which the valves are moving, and opened an exhaust port, with the result that the main valve is moved by steam to the end of its travel and the steam cylinder ports are opened for the return stroke.

Should the main valve by any chance be delayed in being moved by steam, it would be worked mechanically during the clearance in the steam cylinder to a sufficient extent to open the steam port at the end of the cylinder towards which the piston was moving, and so forming a steam cushion to prevent the possibility of the piston striking the cover.

Advantages of the gear are:—

The main and auxiliary valves can all be mechanically actuated from the outside; this is an advantage if the pump is standing for any length of time, as it keeps the faces from getting rusted up.

During the process of the mechanical movement, the piston to which this movement is imparted is in perfect equilibrium.

Entire absence of valve setting.

These pumps are also made on the Tandem Compound principle. Great economy has been obtained with the pumps, and they are specially applicable for electric power stations and other high-class installations where economy of steam is an important consideration.

Fig. 11, p. 1319, shows a pair of these pumps fitted with automatic controlling gear as used

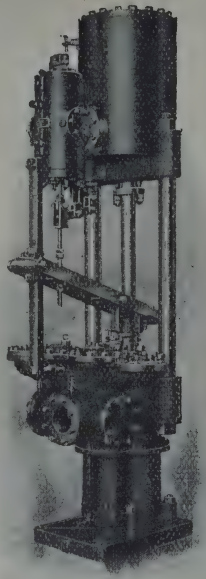

FIG. 9.

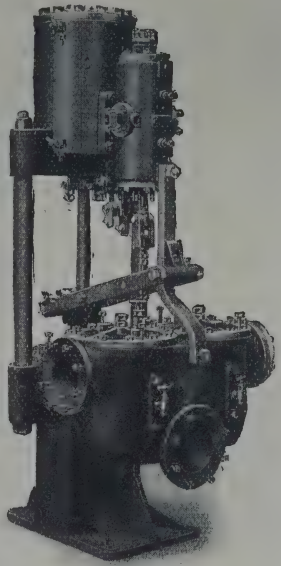

FIG. 10.

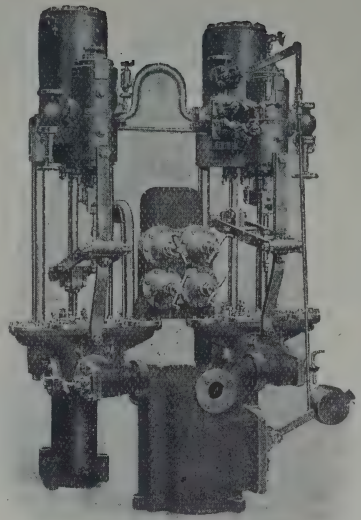

FIG. 11.

for Main Independent Feed-Pumps for Marine Purposes ; with this automatic controlling gear there must be no dead points, and the pump must be able to start from any position, this being a special recommendation for a feed-pump for marine purposes, where, in order to derive all the benefits to be gained by using independent main feed-pumps, the speed of the feed-pumps must be automatically regulated according to the quantity of water to be dealt with, which varies with the speed of the main engines. The 'Woodeson' pump contains all the necessary features for this work.

No flat surfaces exist in any part of the water end exposed to pressure. Both suction and delivery valves are arranged in groups, and are easily accessible for overhauling. The plunger junks are of gunmetal, and are fitted with composition plunger rings, specially manufactured to deal with high pressure and high temperature.

Test taken with Clarke, Chapman Simple Type of Slow Speed Feed-Pump (Woodeson's Patent) :—Diameter of steam cylinder, 10½ ins. ; Diameter of water cylinder, 8 ins.; Length of stroke, 18 ins. ; Water delivered per lb. of steam used, 81 lbs. ; Steam used per water h.p. hour, 59·5 lbs. ; Steam pressure per sq. in., 180 lbs. ; Pressure in discharge pipes per sq. in., 195 lbs. ; Efficiency of pump, 97 per cent.

Test taken with Clarke, Chapman Tandem Compound Type of Slow Speed Feed-Pump (Woodeson's Patent) :—Diameter of h.p. cylinder, 8½ ins. : Diameter of l.p. cylinder, 13 ins. ; Diameter of water cylinder, 8½ ins. ; Length of stroke, 18 ins. ; Water delivered per lb. of steam used, 110·5 lbs. ; Steam used per water h.p. per hour, 36·5 lbs. ; Steam pressure per sq. in., 195 lbs. ; Pressure per square in. in discharge pipes, 215 lbs. ; Efficiency of pump, 97 per cent.

The Caird & Rayner Single-Cylinder Direct-acting Boiler Feed and Service Pump.

The main and auxiliary slide valves of these pumps, figs. 12 and 13 (*Caird & Rayner*), are of the ordinary D type, and have flat wearing surfaces, and are therefore more easily understood and overhauled than those having circular slide valves, and are less liable to leakage. The pistons carrying the main slide valve are subject to end pressure only, so that there is no tendency to sticking, and the wear is practically nil. This obviates the necessity for re-boring worn parts of shuttle casing after working for a period, and the pump does not need to have an extra valve chest supplied as part of the spare gear. Should the water supply be suddenly stopped through any cause, the pump will not unduly race, nor will the piston strike the cylinder ends. The pump is silent in its working.

The main steam-valve admitting the steam to the cylinder ends is the ordinary D type, moving horizontally on a flat face. The auxiliary steam-valve which drives the main steam-valve is of the same type, and moves vertically also on a flat face. The main valve is separate from the small pistons which drive it, so that the pistons are subject to end pressure only, and the wear on them is practically nil. Any little wear on valve faces is taken up by the valves, and, being flat, all easily adjusted and refaced. The auxiliary valve face has ports which lead to the ends of the small cylinder carrying the pistons which drive the main valve. These ports are opened alternately to steam and exhaust, and throw the main valve from side to side. The auxiliary valve is actuated by a lever attached to a crosshead on the pump piston rod. The main steam ports are cast some distance from the cylinder ends, and a small steam port to the extreme end of the cylinder is provided, so that the speed of the pump is reduced when approaching the end of each stroke, thus enabling the pump valves to settle quietly in their seats, and also preventing shock in the feed-pipes. This arrangement of ports also prevents the piston striking the ends of the cylinder should the water supply to the pump for any reason fail, a feature which is of great importance. The pump will start from any point, and the stroke can be adjusted in running by means of the double nuts on the lower valve spindle. The pump valves are arranged in groups, and consist of a number of small valves working on a gunmetal seat. The valves are guided in an overhead frame and have no projections into the seatings, thus permitting a free flow of water and avoiding any side wear in the seatings. The water piston is fitted with ebonite rings, and will run for long periods without adjustment.

The materials of which the various parts are constructed are as follows :—Steam cylinder—close grained cast iron ; steam piston—cast iron or steel, with self-adjusting packing rings ; pump end—close grained cast iron, fitted with gunmetal liner in barrel, or all gunmetal, as required ; piston and pump rods—cold-rolled manganese bronze ; pump bucket—gunmetal, fitted with ebonite packing rings, or as may be desired ; valves and seats—group type of special manganese bronze, working on a gunmetal seat ; columns—mild steel, polished ; valve motion gear—rods and levers of wrought steel, turned bright ; crosshead—gunmetal.

The standard pumps are made suitable for 200 lbs. per square inch boiler pressure.

The Weir Direct-Acting Feed Pump.

The Weir Patent Direct-Acting Feed Pump (*G. & J. Weir, Ltd.*), shown in fig. 14, p. 1323, is the original of a type of pump which is being largely used. Introduced at first for marine boiler feeding, its adoption by the mercantile marine, the British Navy, and numerous foreign navies, caused it afterwards to be placed on the market in a form suitable for land installations, power plants, etc.

The valve gear is positive—*i.e.* the steam valve can never be in such a position that the pump will not start immediately when steam is turned on. The only possible way in which the main valve can rest is at full travel, either for an up or down stroke of the piston. The valve arrangement also ensures constant length of stroke and certainty of action.

THE CAIRD & RAYNER STEAM PUMP.

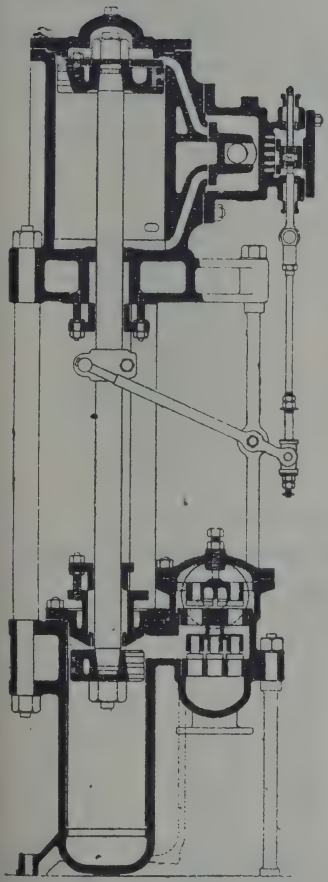

FIG. 12.

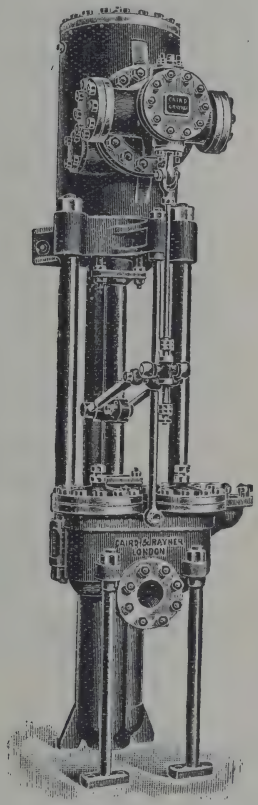

FIG. 13.

The steam valve is practically a D slide-valve, with a small auxiliary valve working on the back, and hence has not the same liability to leak as a piston valve. These are the only two moving parts proper in the steam chest, so that there is little opportunity for wear, and no delicate adjustments to get out of order. The steam is used expansively, and the cut-off can be regulated from the outside while the pump is working.

The water valves are of the Weir group type, providing a large area with only a small lift, thus ensuring easy working and little wear and tear. The pumps are designed to work at a moderate speed and the piston is slowed down towards the end of the stroke enabling the valves to settle quietly in their seats. The working and maintenance of the pumps is therefore much more satisfactory than in pumps running at a high speed. In the matter of steam consumption, numerous tests and comparisons show that the Weir pump is highly economical; this is due to the fact that it has fewer ports and passages than a duplex pump, and the simple expansion arrangement enables it to be built so that the clearance is small.

The parts of each pump are of a standard size, made to gauge and interchangeable, and each complete pump is tested hydraulically and under steam before leaving the works.

Where it is desired to regulate the boiler feed automatically, a special design of float tank and regulating gear is furnished.

The Weir pumps are also supplied of the tandem compound and twin compound types.

Messrs. G. & J. Weir, Ltd., Cathcart, Glasgow, the makers, also list a line of these pumps for light service, tank duty, etc.

List of Parts.—(See fig. 14, page 1323.)

1. Steam slide valve chest.
2. Double joint.
3. Front stay.
4. Bottom spindle.
5. Valve gear levers.
6. Front stay bush.
7. Ball crosshead.
8. Main crosshead.
9. Crosshead pin.
10. Piston rod.
11. Piston body.
12. Piston rings.
13. Cylinder cover.
14. Discharge valve seat.
15. Discharge valve seat ring.
16. Suction valve seat.
17. Suction valve guard.
18. Discharge valve guard.
19. Water valves.
20. Bucket.
21. Pump rod.
22. Pump cover.
23. Valve chest covers.
24. Steam stop valve.
25. Exhaust stop valve.
26. Auxiliary valve spindle.
27. Cylinder neck ring.
28. Cylinder gland.
29. Pump neck ring.
30. Pump gland.

THE WEIR DIRECT-ACTING FEED PUMP.

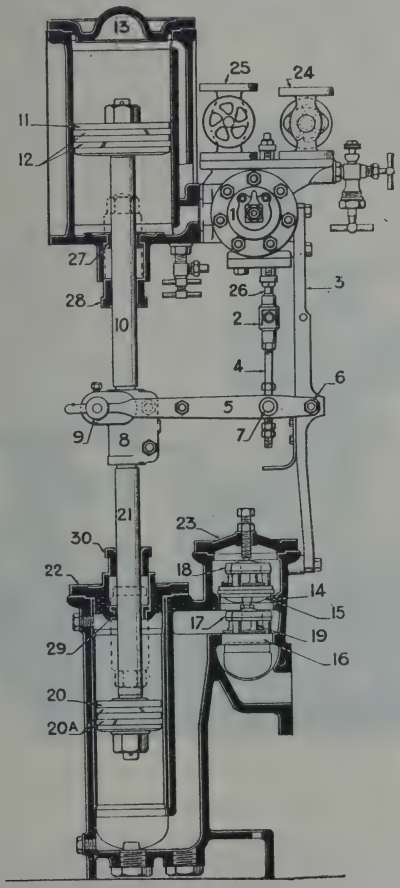

FIG. 14.

The Weir 'Turbo Feed' Pump.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

This pump, fig. 15, consists of a single pressure, multivelocity stage, impulse steam turbine, working in conjunction with a single stage centrifugal pump of special design.

The turbine casing and bearings are divided horizontally, the lower portions being embodied in the general framework or base of the set. This framework is extended at one end to form a flange, to which the pump casing is rigidly secured. By this arrangement the impeller of the pump is carried on the overhanging end of the turbine shaft.

By means of a suitable hydraulic governor, operating a balanced double beat throttle valve, the set is self-regulating for all ordinary changes in both water and steam conditions. When the latter are decidedly adverse, auxiliary nozzles may be brought into play by means of auxi-

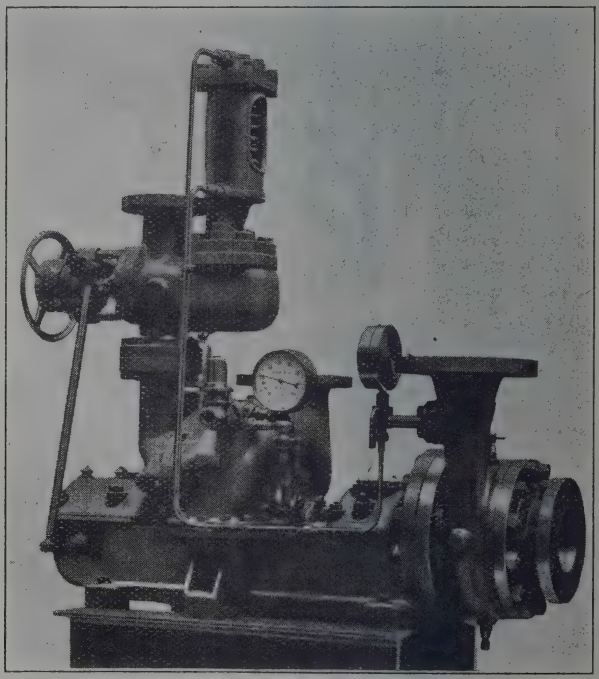

Fig. 15.—The Weir 'Turbo Feed' Pump.

liary valves in the nozzle box and the quantity of steam supplied to the turbine considerably augmented.

An emergency governor of the eccentrically-loaded ring type is provided, which, in the event of the speed of rotation exceeding a predetermined limit, actuates a trip gear which releases a spring and instantaneously closes the stop valve, and steam is completely shut off from the turbine. Thus there is no possibility of the speed of the set reaching unsafe limits in the event of an accidental failure of the supply; and as the discharge pressure depends upon the pump speed only, the set cannot be seriously overstrained by sudden obstruction or closing of the discharge.

The turbine glands are provided with carbon packing, the bearings are of the self-oiling ring type, and the pump impeller is hydraulically balanced.

The Weir Turbo Feed Pumps are of sound mechanical construction and all parts are readily accessible for examination and overhauling. They are entirely automatic in action and are noiseless and free from vibration.

The WEIR TURBO FEED PUMP

Compact—Reliable—Self-regulating.
Suitable for either saturated or superheated steam—Oil-free Exhaust.
Presented in standard sizes capable of dealing with from 7000 to 75,000 gallons per hour to boilers working at pressures varying from 100 to 1200 lbs. per square inch.

Our booklet 'The Weir Turbo Feed Pump' gives you full particulars.

Nine Elms Iron Works,
READING.

The pumps are capable of discharging against the highest boiler pressures and are specially suitable for large units. They can be used to work in conjunction with ordinary reciprocating pumps.

A special feature of the Weir Turbo Feed Pump is its economy in steam consumption. Further, as the exhaust steam contains no oily residue, it is available for heating the feed water by direct contact, thereby utilising all the heat in the steam. In this connection Messrs. Weir have introduced a nozzle heater which has been specially designed for working in conjunction with these pumps.

The Weir Roto-Feed Pump has been adopted by the British Admiralty and the leading Municipalities and Electric Power Corporations, including the Corporations of Cardiff, Glasgow, Greenock, Halifax, Norwich, Poplar, Salford, West Ham, Wolverhampton, Woolwich, the Clyde Valley Electric Power Co., and Treforest Electrical Consumers, Ltd.

The Pulsometer Steam Pump.

In this pump (*The Pulsometer Engineering Co., Ltd.*), figs. 16 and 17 (general view), the neck J contains a gun-metal ball I, above which is a steam pipe K. EE are suction valves placed at the base of two chambers AA. Immediately above the suction valves the two chambers com-

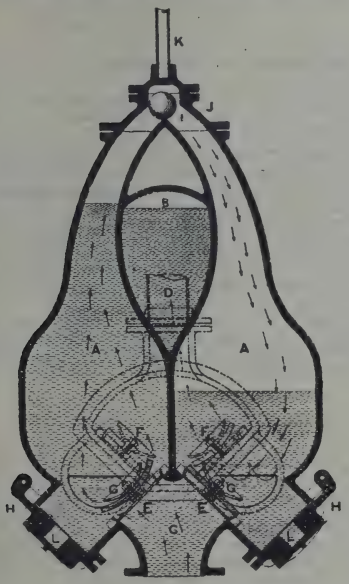

Fig. 16.

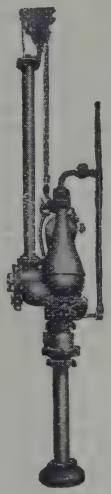

Fig. 17.

The Pulsometer Steam Pump.

municate with a 'discharge box' through two discharge valves FF. The valves in the standard pattern of pump are of the grid type, consisting of a grid, rubber, and guard. In addition to the above valves there are three small gun-metal valves (not shown in the figure) for the admission of air, one of each being screwed into the upper part of the two water chambers and the air vessel.

Action.

Assuming one of the chambers to be open to steam and full of water, the steam entering by the steam pipe and past the ball passes into the chamber and presses upon the small surface of water exposed, depresses it without agitation (and therefore with little condensation), and drives it (as seen in the figure) through the discharge valves FF into the rising main, D. The moment the water in the chamber falls to the level of the opening in the branch leading to the discharge box, the steam blows through with a certain amount of violence, and as it is brought into intimate contact with the water in the discharge box an instantaneous condensation takes

place, and the vacuum thus formed in the emptied chamber immediately pulls the control ball over on to the corresponding seat and cuts off further admission of steam, allowing the vacuum to be completed. Water immediately enters through the suction pipe, and lifting the inlet valve rapidly fills the chamber again. A similar operation has been taking place in the fellow chamber, the period occupied by filling one chamber corresponding to that of emptying the other, and these operations continue alternately in the two chambers so long as the pump is supplied with steam and water. The function of the air valves is to introduce a small quantity of air at each stroke or 'pulsation' for the purpose of cushioning the ball when it changes its position, and for separating the steam from the water by a non-conducting film so as to prevent loss by condensation during the expulsive portion of the cycle.

The 'Pulsometer' Steam Pump will work just as well suspended from a chain or rope as when permanently fixed. Its very small size, in proportion to the quantity of water thrown, makes it available in a great many situations where no other pump can be applied. Another important feature is its ability to pump water heavily charged with mud and sand. For these reasons it is very largely used by contractors for pumping from excavations.

The 'Pulsometer' Steam Pump will, where the conditions remain constant, work day and night without attendance—in fact, as long as steam and water are supplied to it.

Boiler Pressure Required for Pumping.

What boiler pressure would be required to operate a direct-acting steam pump having an 8-in. diameter steam cylinder and a 6-in diameter water cylinder, for pumping water to a height of 100 ft. with the suction water supplied at a pressure of 10 lbs. per sq. in.?

The mechanical efficiency of a pump of the stated size, when in good working order, would be about 65 per cent. The pressure pumped against would be $100 \times 0{\cdot}433 = 43{\cdot}3$ lbs. per sq. in. due to the head, plus the pressure required to overcome friction of the water in the discharge pipe, the latter depending on the rate of pumping, and the diameter, length, and fittings of the discharge pipe. Under ordinary conditions the loss of pressure from pipe friction would be no greater than 10 lbs. per sq. in., and if assumed to be equal to the suction pressure the net resistance to movement of the water piston would be $(6 \times 6 \times 0{\cdot}7854) \times 43{\cdot}3 = 1{,}224$ lbs. With 65 per cent. mechanical efficiency of the pump, the resistance to be overcome by the steam piston would be $1{,}224 \div 0{\cdot}65 = 1{,}883$ lbs., and for overcoming that resistance the effective pressure required to be exerted on a direct-acting 8-in. diameter steam piston would be $1{,}883 \div (8 \times 8 \times 0{\cdot}7854) = 37{\cdot}46$ lbs. per sq. in. The required boiler pressure will need to be equal to the effective pressure plus the back pressure and the reduction of the boiler pressure by throttling in the steam pipe and steam passages of the pump. Allowing a back pressure of 4 lbs. and reduction by throttling of 10 lbs. per sq. in. would require a boiler pressure of $37{\cdot}46 + 4 + 10 = 51{\cdot}46$ or about 52 lbs. per sq. in.

Willcox-Penberthy Cellar Drainer.

This is a Water Pressure Ejector (*W. H. Willcox & Co. Ltd.*) of high capacity, for use in removing water from cellars, inspection pits, stokeholes, lift pits, or wherever it is desired to keep water or other liquids from rising above a certain level. It is automatically operated by a float-controlled, quick opening and closing valve. This valve is never partially opened; it cannot leak, and allows the ejector to give its greatest efficiency by working to full capacity. The float arm is slotted where it connects to the valve lever; this prevents the ejector from operating until the water has raised the float up to the highest point, and, as the water is ejected, the arm travels down the length of these slots before the weight of the float affects the valve.

To facilitate the installation of this drainer in small holes or sumps it is made as compact as possible. The float, instead of being round, is flat on the top; this gives it more buoyancy and occupies less space than would a round float of the same diameter. To further economise space the float is built around the suction pipe. This arrangement (patented) has the advantage of being rigid, and overcomes all the trouble of a loose float. The balance of the drainer is built directly above the float; this not only keeps the whole machine in as small a space as possible, but also keeps all working parts, with the exception of strainer and float, above the water, thus preventing corrosion or the exterior parts becoming clogged up by deposits of slime, dirt, or sediment. The interior parts are prevented from coming into contact with any foreign particles by a special strainer, which is so constructed that instead of the water being drawn directly upward, it is taken in at the sides, allowing all sediment to collect under the strainer without being disturbed by the force of the suction. A foot valve is provided inside the strainer, which closes the instant the drainer ceases operating, holding all water in the pipes, all primed for starting instantly at the next filling of the sump.

The following tables show the capacities at different pressures and elevations, dimensions, pipe sizes, weights, etc.:

TABLE OF CAPACITIES OF WILLCOX-PENBERTHY CELLAR DRAINERS AT DIFFERENT PRESSURES AND ELEVATIONS, PIPE SIZES, ETC., MODEL 'R.'

Size and Model.	Pipe Sizes. Ins.		Working Head in ft.	Maximum Net Capacities from Sump, in Gallons per Hour at 10 to 100 lbs. Water Pressure.

			9		1260	1960	2600
			12			1560	2060
			18				1500

The above capacities are the actual capacities of water taken from sump, and not the combined discharge of operating and drainage water as given in most tables. For higher elevations than shown above, special drainers can be made.

Pump Valve Materials

Dexine.

Dexine (*Dexine, Ltd.*) is a preparation of vulcanised indiarubber and other ingredients manipulated by a special process; it is an exceedingly tough and frictionless material which has been proved to withstand the action of oils and chemicals. It is extensively used for valves, in the place of ordinary indiarubber, and can be obtained in any degree of hardness, suitable for straight or curved guards and pumps of all descriptions and of all dimensions.

Valves made of Dexine are claimed to retain all the resiliency and natural cohesion of pure Para rubber—which enters into its composition to a certain extent—and is, in addition, rendered immune from the detrimental influence of acids, oils, alkalies, or grease. The material can be moulded to any shape, and vulcanised to any degree of hardness or flexibility to suit any particular purpose.

Dexine is also used to form the 'bucket or cup leathers' of pumps, up to 20 ins. diameter. In round or square section, or in the form of U rings, the material makes an efficient packing for compressor rods, and, having a low coefficient of friction, the wear on the material is very slight.

Hydraulic Packings.

Ram or 'U' Leathers.

A cupped leather packing (ram or 'U' leather) forms a self-tightening packing, and is very generally used, although if it is not properly made, and if the cup is not strengthened at the bend (where the greatest friction is), the leather soon wears out and fails.

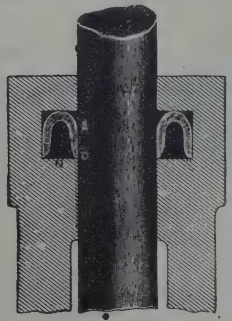

FIG. 18.

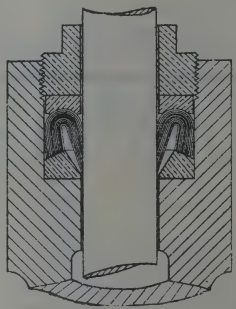

FIG. 19.

Fig. 18 shows a ram leather in its position. The water gets behind the leather and presses it tightly against the ram; the friction occurs mainly at part A, and increases as the pressure of water increases. There is not much friction at the portion between A and B, and the efficiency of the press is but little altered by making AB greater or less. It is, however, asserted by some that the distance AB is of importance, but this is on account of deterioration. The part AB is constantly in states of tension and compression, and if the leather is not good and well made it is liable to crack. Leathers are very frequently made too deep, and this leads to their being more liable to crack and fail; a shallow leather is undoubtedly the best—it works just as well as a deep one, and in making the leather considerably less strain or pull is required to block or mould it than would be the case with a deep one.

Too much stress cannot be laid on the necessity for using leather packings of the best quality and make only. It is equally important to consider the question of tannage. The value of a tannage depends upon its suitability and adaptability for different classes of work. Low pressure work, for example, requires a different tannage and fibre from high pressure and medium pressure a tannage and fibre between the two.

Fig. 19 shows a Patent 'SEA' Ring of compressed cotton layers supplied for packing purposes.

Pump Leathers and Packings.

'SEA' rings are specially designed with a view to a higher efficiency than may be obtained by the use of the ordinary leathers. Fig. 20 shows a double-acting plunger fitted with two 'SEA' ring cups separated by metallic junk-ring, and fig. 21 shows a 'SEA' ring collar fitted to a hydraulic or other ram. It is claimed that these ring packings will wear indefinitely where the ordinary leather would wear out and crack in a very short time. The rings are able to resist high temperatures, and are used with success for extremely high pressures. They are

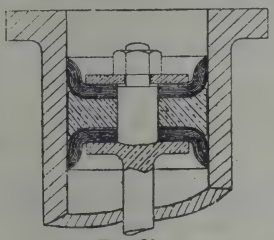

Fig. 20

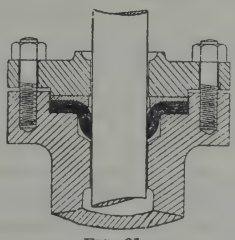

Fig. 21.

obtainable in sizes varying from those suitable for cylinders of 1 in. up to 9½ ins. in diameter and of various sections according to the specific purpose for which they are required.

Notes on Hydraulic Leathers.

Corrosion is one of the principal annoyances of hydraulic power, and bad water is responsible for fully 50 per cent. of wear and tear and repairs. Chalybeate water (that is, water containing iron) is about the worst.

Where dirty or gritty water has to be used the leathers wear away very rapidly. When the leathers are not kept constantly under pressure, if the pressure is taken off, the water gets between the leather and the ram, and as soon as the pressure comes on again, a little gritty or dirty water passes between the leather and the ram and causes the wear of the packing; it also scaives or flutes the ram. A remedy for this consists in putting a relief valve on the pipe that delivers the water to the accumulator from the pump, and in leaving the suction valve always open. The pressure in this way is always kept on the leather, preventing leakage, and at the same time saving considerable wear and tear of the packing.

It is important and essential that a leather should be well rubbed and worked with tallow before putting in. A good plan is to fill the inner space of the leather with neatsfoot oil or sperm, about an hour before putting in. *Never use mineral oil for rams or cylinders*, it runs away quickly, through being thin, and also renders the leathers rotten and pulpy.

For lubrication, Entwistle's patent lubricant (Patent No. 16,292; 1894), which contains 50 parts stearine or tallow, or other similar substance, 20 parts soapstone or powdered mica or talc, 2 parts graphite, 10 parts neatsfoot or other oil, 10 parts powdered zinc, lead, copper, or other soft metals, and 10 parts oil of tar, has given excellent results; the particles of metal, by the motion of the ram up and down, fill up any indentations, pores, or rough surfaces there may be on the ram or in the cylinder, and being of a soft or yielding nature (not gritty) distribute themselves over the rough surfaces.

Friction of Accumulator Cup Leathers.

The loss by friction in pumping into an accumulator is a very doubtful quantity and has not been satisfactorily determined. Various formulæ have been given, but a very wide divergence exists between them, probably due to the fact that the friction varies very greatly with the smoothness of the ram—whether it is rusty or not—the nature of the leather, also as to whether it is clean or sticky, and whether the ram is stationary or sliding, and whether the ram is perfectly centrally loaded—if the load is only a very small amount out of the centre of the ram it tilts it and materially increases the friction.

The formula due to 'Hicks' gives a result which makes the friction but one-sixteenth of that given by another formula due to Professor Goodman, and even the latter formula has been questioned as giving results much too low.

CENTRIFUGAL PUMPS.

V = velocity of the periphery of fan, in feet per second. H = height, in feet, to which water is to be raised. R = revolutions per minute of fan. D = diameter of fan, in inches. W = width of fan at the periphery, in inches. d = diameter of discharge-pipe, in inches. n = number of blades. t = thickness of blades. G = gallons per minute. E.H.P. = effective horse-power required.

$$V = 8{\cdot}8\sqrt{H}, \text{ for small fans, to } 10{\cdot}5\sqrt{H} \text{ for large fans.}$$

Another formula is—

$$V = 8{\cdot}8\sqrt{H} + K, \quad \text{where } K = 5 \text{ to } 10.$$

The last formula gives good results, varying the coefficient K with the height of lift.

$$R = \frac{V \times 230}{D} = \frac{(8{\cdot}8\sqrt{H} + K) \times 230}{D}. \qquad D = \frac{(8{\cdot}8\sqrt{H} + K) \times 230}{R}.$$

$D = 1{\cdot}5d$. to $5d$. $\quad d = \frac{\sqrt{G}}{4}$. $\quad W = \frac{d^2}{4D - 1{\cdot}27nt}$. $\quad E.H.P = \frac{G \times 10 \times H \times \frac{5}{4}}{33000} = G \times H \times {\cdot}00076.$

(The fraction $\frac{5}{4}$ represents 40 per cent. efficiency.)

EXAMPLE.—What size of pump is required to lift 4,000 gallons per minute to a height of 15 feet?

First find velocity, V, of periphery of fan. Taking 6 as a mean value for K, then $V = 8{\cdot}8\sqrt{15} + 6 = 34{\cdot}08 + 6 = 40{\cdot}08$ feet per second, or, say, 40 feet per second.

Diameter, d, of discharge-pipe at 4,000 gallons per minute, G, $= \frac{\sqrt{4000}}{4} = 16$ inches.

Taking $D = 3d$ as a mean value, then $D = 3 \times 16 = 48$ inches.

Number of revolutions per minute, R, $= \frac{8{\cdot}8\ (\sqrt{15} + 6)\ 230}{48} = 192.$

Taking 6 blades (n), each having a thickness, t, of $\frac{1}{2}$ inch, then

$$\text{Width, W, of fan} = \frac{16 \times 16}{(4 \times 48) - (1{\cdot}27 \times 6 \times \frac{1}{2})} = \frac{256}{192 - 3{\cdot}81} = 1{\cdot}36 \text{ inches.}$$

The greater the diameter of the fan, the less number of revolutions it requires to make.

The speed of the water through the pipes should not much exceed 8 feet per second. In many pumps the speed is greater (10 feet per second); but this is too high for good practice.

In all cases the efficiency of a pump will be increased by a tapering enlargement of the discharge pipe to as large a diameter as convenient. Such a taper pipe should be very slowly tapered, say about 1 in 8 times its initial diameter.

The best speed to drive centrifugal pumps is a much debated question. For mine use moderate speed is preferable wherever possible, as less trouble is then experienced with both pump and motor. In other cases the higher speed pumps give good service. For 75 or 100 h.p. and upward 900 r.p.m. is satisfactory; for 30 to 50 or 75 h.p. 1,200 r.p.m., and for smaller pumps 1,500 to 1,800 r.p.m. (*H. Axford in 'Coal Age.'*)

Classification of Centrifugal Pumps.

Generally speaking, centrifugal pumps may be classed in two groups, namely :—(*a*) Without guide wheels; (*b*) with guide wheels.

(*a*) In pumps which are *not provided with guide wheels* (fig. 22), the casing is constructed

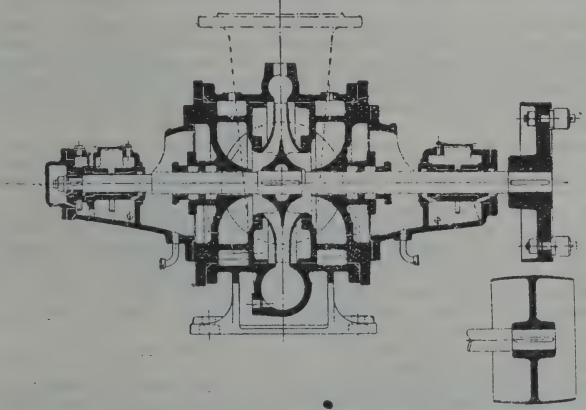

Fig. 22.—Section through Centrifugal Single-stage Pump (Low-lift or Medium).

with a spiral-shaped channel with gradually widening sectional area, which acts as a diffuser These pumps are usually termed low-lift and medium-lift centrifugal pumps, and have, as a rule one—sometimes two—stages. The pressure they produce ranges up to about 300 ft. water column.

(*b*) For pressures above 300 ft., as required for hydraulic service, mine drainage, boiler feeding waterworks, etc., three, four up to ten impellers are arranged in series and all built in the common casing (for extraordinarily high pressures two cases might be used).

With these high-lift pumps (fig. 23) the water passes through each impeller in turn, and is directed from one impeller to the next following and from the last into the delivery branch of the

pump through specially designed *guide wheels*, converting into pressure, without shock, the bulk of the kinetic energy transmitted to the water by the impellers. Each stage of the pump contributes equally to the total pressure. The design of the diffuser guide wheels and the blades of the impellers, i.e. the passages through which the water travels with a high velocity, is mainly responsible for the degree of efficiency attained by a centrifugal turbine pump. The steady flow of water through the pump, with as few changes in velocity as possible, avoiding shocks and eddies with inherent friction loss, is of the greatest importance. The clearance between the rotating and stationary parts in the pump must be so dimensioned that too much water cannot flow back from one stage to the preceding one. The balancing of the axial thrust produced in multi-stage pumps is also important.

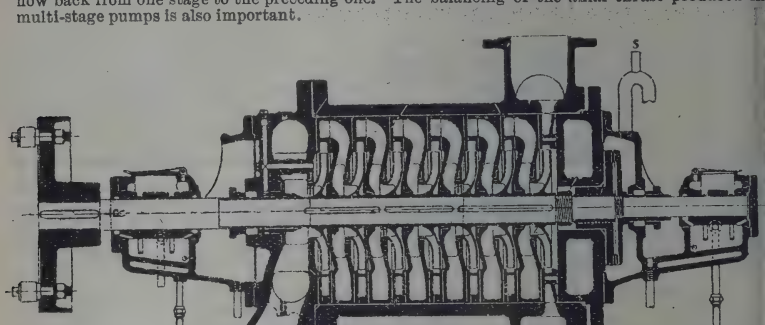

FIG. 23.—Section through Centrifugal High-lift Pump.

There are practically no limits as regards the pressure heads that high-lift centrifugal pumps cannot overcome (some makers, for example, have supplied pumps delivering to 3,500 ft.), as long as the quantity to be delivered is not too small. The manometric suction head should, for hydraulic reasons, not exceed about 18 ft., as otherwise the efficiency may be reduced and wear in the first stage be caused. For hot liquids the suction water should flow from a higher position into the pump, this height being determined by the fact that no evaporation must take place in the suction pipe.

The characteristics of the centrifugal pump are in many respects different, even the reverse, to those of the piston pump. Thus a centrifugal pump can run with the delivery valve shut, producing no dangerous pressure. Generally speaking, at a constant speed with increase in quantity the pressure produced falls, or, in other words, a reduction in the pressure which the pump has to overcome will result in a greater quantity being delivered. Great care should therefore, be taken in ascertaining, as accurately as possible, the head for which a pump is to be built, as otherwise the pump will possibly not come up to expectations as regards capacity or if the head upon which the designer based his calculations is greater than the actual head against which the pump has to work, a larger quantity will be delivered by the pump and the load on the driving motor increased.

No bearings should be permitted inside the pump; they should be carried in brackets outside the casing. Stuffing-boxes should not be used as bearings.

Under specially favourable conditions a centrifugal pump made by a first-class firm should attain efficiencies up to 86 per cent.

Centrifugal pumps sometimes will pick up water for a few seconds, as shown by the discharge gauge, and then lose the suction when the discharge valve is open. The reason for loss of suction generally is a large amount of air which is drawn in through the glands or suction pipe in some way. Air sometimes may be drawn in through the suction pipe, although it is entirely submerged beneath the level of the water. This is due to some extent to the vortex or whirling of the water around the suction pipe, thus forming an open passage to the air above. The cure lies in reducing the velocity of water in the suction pipe, either by adding a bell-mouth or tee, etc., or by drilling a number of holes into this pipe.

SOLID MATTER CENTRIFUGAL PUMPS.

See Vol. COVIII. (Dec. 1920), 'Minutes of the Proceedings of the Institution of Civil Engineers,' pages 275–346, and *Engineering*, Jan. 20, 1922.

The impellers in these pumps have flexible blades.

Packing of Centrifugal Pumps.

About nine-tenths of the trouble with centrifugal pumps is due to improper packing. Square ax is generally used, and this soon wears hard, cuts the shaft, leaks badly, and has to be replaced requently at considerable expense. Soft-flax packing soaked in oil and graphite gives better esults, but it lasts only a short time. A 5 in. double-suction centrifugal pump direct-connected o a 15 horse-power motor running at 1,800 revolutions per minute, supplying a barometric con- enser, experienced considerable trouble owing to the packing wearing out, the pump taking air, osing the water, and the vacuum ; this pump being packed with rawhide packing, after two nonths' continuous running was found not to leak. The rawhide packing is very economical, s the old packing does not have to be pulled out, and a new ring can be put in on top of the ld and kept in the box till it is completely worn out, also the shaft is kept in a good condition.

(*Power.*)

The 'United States' Patent Rotary Packing.

This packing is intended primarily for rotating shafts of centrifugal pumps, etc., and its rincipal feature is that it causes no friction whatever to the shaft, whilst providing an arrange- ient which will run for a considerable period without requiring renewal. It tends to increase he efficiency of the pump, and obviates any wear on the shaft.

The packing is made in two portions, one portion being for attachment to the casing, whilst he other is clamped to the shaft and rotates therewith. In this rotating portion the packing ings proper are fitted, and as these are not subjected to any friction they should last indefinitely. The two portions of the packing are always held in contact, and the friction which arises s restricted to the two surfaces (as between the fixed and the rotating portions) thus affected, ut as one of these surfaces is of anti-friction metal, and provision is made for lubrication at this oint, the wear is slight, and, as above stated, the packing gives considerable service before enewal of the anti-frictional part becomes necessary.

To facilitate the fitting of this patented packing, the component parts can be supplied in isected form, when so required.

A special lubricator is furnished at slight additional cost. This is pressure operated, and naintains a feed of oil to the surfaces in contact all the time the pump is running, but ceases o operate when the pump is stopped.

It is claimed that a 20 per cent. increase in efficiency of centrifugal pumps has resulted from he adoption of this device.

The packing is absolutely air-tight, whilst it causes no friction whatever to the shaft.

The Pulsometer Centrifugal Pump.

(*The Pulsometer Engineering Co., Ltd.*)

This pump, fig. 24, is specially adapted for low lifts at moderate speeds. The suction is central t one side of the pump. The discharge branch can be fixed at various angles to suit the direction f the pipes. The bed, casing, and impeller are of cast iron. Gun-metal impeller, slip rings,

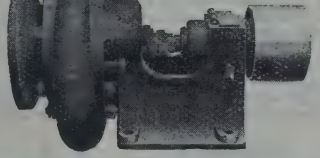

Fig. 24.

enewable bronze sleeve on shaft, or rustless steel shaft can be supplied at an extra price. Sufficient thickness of metal is allowed in the covers where the impeller is in running contact to permit of their being bored out and slip rings fitted when wear takes place. When dealing with dirty water slip rings should be fitted in the first instance. The shaft, which is of high carbon steel and of large diameter, is of ample strength to permit of driving by the overhung pulley. The bearings are of cast iron lined with white metal, the lubrication being continuous by means of a revolving ring dipping into a large reservoir fitted with oil overflow and drain. Creeping of the oil is prevented by collars fixed on the shaft. The stuffing box is fitted with a gun-metal neck bush, and is cooled and lubricated by water. It is sealed with water under pressure, which prevents the ingress of air when the pump is working with a high suction lift, but the stuffing box can be sealed with grease by fitting a lubricator for semi-solid lubricant.

Centrifugal Pumps for Hot Water.

Centrifugal pumps, when designed for pumping hot water, are quite satisfactory for feeding boilers. When used for this purpose, however, the intake pipe must be about three times as large as it would ordinarily be for cold water. Sharp turns and constricted passages, both in the pump

itself and in the connecting pipework, must be avoided in order to prevent the release of steam at the constricted points. This trouble generally occurs when there is a sudden demand for water. In addition the efficiency of the pump is lowered and difficulty is also encountered in maintaining the supply of water. (*W. E. Warner*, '*Cheap Steam*,' July 1927.)

Turbine-Pumps.

The 'Pulsometer' High-Lift Turbine Pump.

(*The Pulsometer Engineering Co., Ltd.*)

In this pump, fig. 25, the axial thrust is taken up inside the pump by a balancing disc fixed on and revolving with the spindle.

The periphery of the disc moves in close contact with a seat fixed to the delivery cover. The space enclosed by the disc and its seat is supplied with water under pressure from the last cell, and this water passes out between the periphery of the disc and the seat into the chamber in which the disc revolves, and then through a connecting pipe back into the suction pipe.

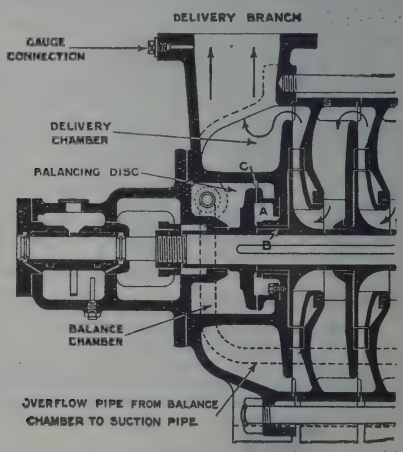

FIG. 25.

There are no collars on the spindle at the bearings, so that it is free to move axially when the pump is not working, but when working the balancing disc keeps it in position. This system of balancing has the further great advantage that the stuffing box at the delivery end is exposed to suction pressure only, no matter what pressure the pump is working against.

The impellers are not balanced, and the unbalanced area of each impeller causes an axial thrust towards the suction cover. It is this thrust that the balancing arrangement successfully overcomes in the following manner:

The chamber A is supplied with water under pressure from the last impeller, through the clearance B between the spindle and the centre bush in the delivery cover.

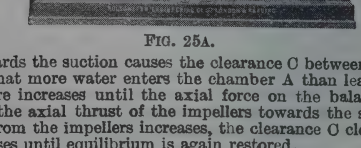

FIG. 25A.

The axial thrust towards the suction causes the clearance C between the balancing disc and its seat to close up, so that more water enters the chamber A than leaves it, and the pressure in this chamber therefore increases until the axial force on the balancing disc towards the delivery cover balances the axial thrust of the impellers towards the suction cover.

As the axial thrust from the impellers increases, the clearance C closes up, and the pressure in the chamber A increases until equilibrium is again restored.

As the pressure in the chamber A increases, the clearance C opens, and the pressure in the chamber A is reduced until equilibrium is restored.

The balancing disc is made so large that there is no danger of its coming into contact with its seat even under the most unfavourable conditions of pumping, such as when the pump is running at full speed with no head.

As there is no metallic contact there is no wear, except when gritty water is pumped, and when from this cause the wear has become excessive, the disc or its seat, or both, can be replaced in a very short time and at small cost, without dismantling the pump, it being only necessary to remove the bearing.

Fig. 25A shows a general view of one of these pumps.

THE 'VSG' MARK III. VARIABLE DELIVERY PRESSURE PUMP.

(*The Variable Speed Gear, Ltd.*, 6, *Broadway, Westminster, S.W.* 1.)

This pump is of the 'Williams-Janney' or horizontal piston type. Fig. 26 shows a vertical section through the latest design (arranged for lever control).

The 'mainshaft' is driven in one direction, and carries a rotating block or 'cylinder barrel' mounted on it by a universal joint and which is free to move axially.

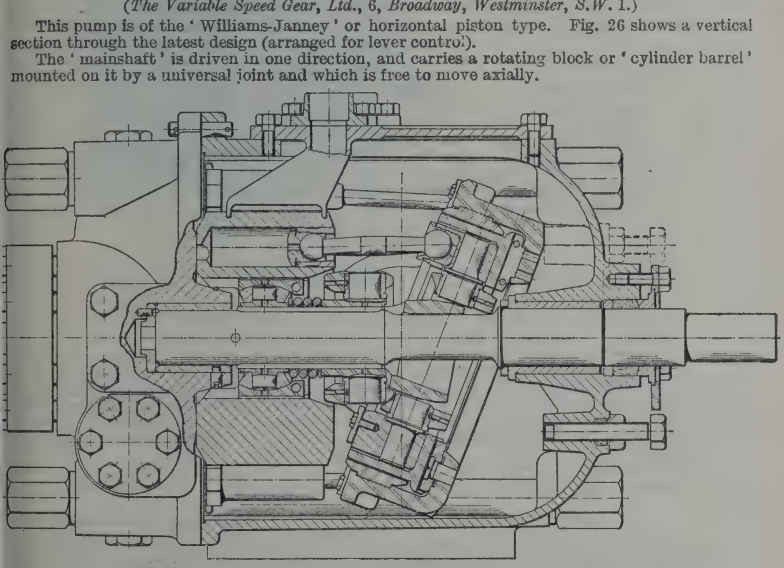

FIG. 26.

This 'cylinder barrel' contains cylinders bored parallel with the mainshaft, having ports of reduced section opposed to two kidney-shaped ports contained in the face of the 'valveplate,' which is stationary.

The 'cylinder barrel' rotates in contact with the 'valveplate' face in a state of hydraulic balance, initial contact being obtained by spring loading.

Each cylinder is fitted with a 'piston' connected by a ball-ended rod to the 'socket ring,' which in turn is connected to the 'mainshaft' by a double universal joint.

The 'socket ring' rotates in a non-rotatable but pivoted member called the 'tilting box,' 'Michell' type bearings being interposed to take the thrust and radial load. When the 'socket ring' is vertical the pump is in the neutral or no-stroke position, but any deviation from the vertical imparts stroke to the 'pistons' and causes delivery through one of the 'valveplate' ports and return through the other.

The greater the tilt the more delivery given, owing to the increased travel of the pistons. By reversing the angle of tilt the flow will also be reversed, and what was previously the delivery port will become the return port.

Lever or wheel controlled pumps can be arranged to give delivery in both directions from zero to maximum, but in the case of pumps fitted with auto-pump control, as applied to operate rams, etc., tilt is usually applied in one direction only, and the flow from these pumps is therefore not reversible.

Two distinct types of pumps can be supplied, viz. :—

Lever or Wheel controlled Pumps.	To give variable delivery at fluid pressures up to the maximum pressure at which the relief valves are set, controlled by hand or mechanical means.
Automatic Pressure controlled Pumps.	To give automatically regulated delivery over a predetermined pressure range, or alternatively at a practically constant pressure. Delivery is controlled by the pressure of the fluid in circulation acting on rams connected to the top of the tilting box opposed to springs acting on the base of the tilting box.

This pump also forms the 'A' end unit of the hydraulic transmission gear manufactured by this Company (*The Variable Speed Gear, Ltd.*), described on pp. 1032-1034.

The Stone Turbine Pump.

(J. Stone & Co., Ltd., Deptford, S.E. 14.)

These pumps are made in seven sizes, varying in capacity from 100 to 1,500 gals. of water per min., the maximum head on the smallest size, with eight stages, being 360 ft., and with the largest size 1,600 ft.

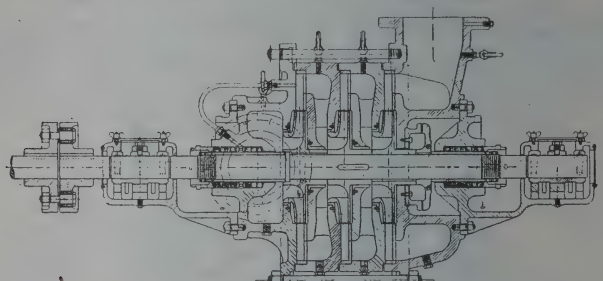

FIG. 27.

The construction adopted is of the sectional type (fig. 27), which enables the pump to be built up to any number of stages up to the maximum. The sectional construction also possesses the very great advantage that leakage between the stages can be at once detected, and the pump can be easily dismantled on site. This construction is usually preferred by mining engineers to the solid-casing type of pump, as with the latter it is impossible to detect leakage between the stages, and also, with the solid-casing type of pump, internal rusting is likely to cause difficulty in dismantling.

The impellers and guide vanes are usually supplied in Stone's special 'No. 1 Bronze,' which is free from zinc and has proved very successful in withstanding the action of gritty and acid

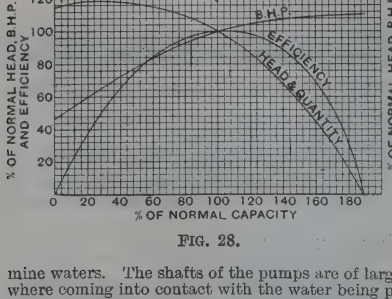

FIG. 28.

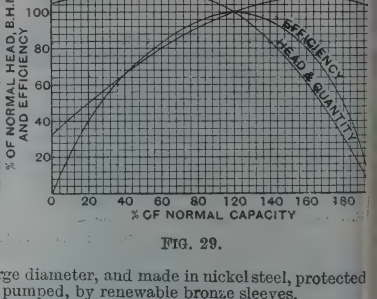

FIG. 29.

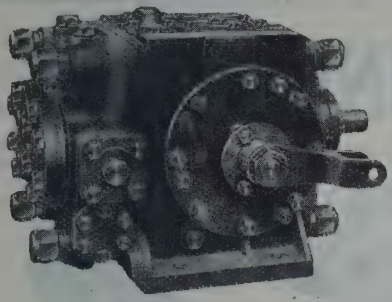
mine waters. The shafts of the pumps are of large diameter, and made in nickel steel, protected where coming into contact with the water being pumped, by renewable bronze sleeves.

Curves, figs. 28 and 29, show the characteristic curves of the pumps plotted on a percentag basis, and from which curves the performance of any individual pump, when working on an other duty than normal, can be readily seen.

Example.—An MS. 6-2 stage pump is designed for 550 gals. per min., and 200 ft. head, with a efficiency of 72 per cent., taking 46·5 b.h.p. at coupling to drive. What would be the performanc at a head of 170 ft. ?

170 ft. corresponds to 85 per cent. of the normal head, and referring to the curve marke 'Head Quantity,' for pump sizes 6 ins. and above, the curve shows that the capacity has increase to 119 per cent. of normal, or, say, 655 gals. per min. Referring to the 'Efficiency' curve for thi percentage increase in capacity, the curve shows that the efficiency is 95 per cent. of the norma which is 95 per cent. of 72 per cent., or, say, 68 per cent. efficiency. From the 'Brake-horse power' curve it will be seen that the power required to drive is increased to 106 per cent. of norma or, say, 49·5 b.h.p.



"VSG Mark III" Variable Delivery Pressure Pump fitted with Lever Control.

"VSG"

VARIABLE DELIVERY PRESSURE PUMPS

SUITABLE FOR ALL SYSTEMS EMPLOYING OIL AS THE HYDRAULIC MEDIUM

Two types of Pumps can be supplied :—

1. To give variable delivery at fluid pressures up to pre-determined maximum, controlled by hand or mechanical means.
2. To give delivery over a pre-determined pressure range, controlled automatically.

Extensively applied for operating Gun Mountings, Steering Gears of Naval and Mercantile Vessels, also Hydraulic Presses, Shears, Riveters, Control Systems, Lifts, etc.

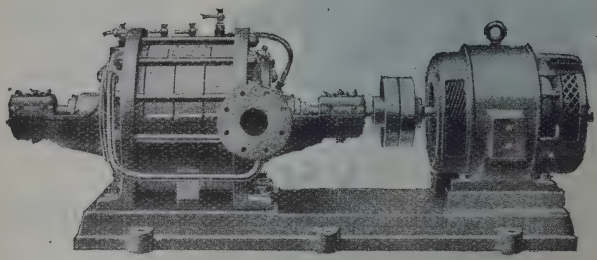
HIGH EFFICIENCY

TURBINE PUMPS



Correct Hydraulic Design.

Sound Mechanical Construction.

Best Material and Workmanship.

Impeller and Diffusion Vanes cast in Stone's No. 1 Bronze.

End Thrust Hydraulically Compensated.

Standard Designs up to 3,000 ft. head, from 90 to 1,500 G.P.M.

Full particulars will be sent on request.

J. STONE & COMPANY LTD

Deptford, London S.E. 14.

Makers of Pumps for all Duties.

F. 1337

The pumps have the advantage that neither the suction nor delivery gland is under high-pressure water, the gland at the suction end being water-sealed, and at the delivery end the balance valve reduces the pressure across the gland. By this construction the stuffing-boxes need only be packed lightly, to reduce leakage to the minimum amount; it also means less friction and absence of wear on the shaft sleeves, and consequent higher pump efficiency.

The end thrust is compensated by the standard design of balance valve. Both the balance valve and seating are made in hard bronze, and are easily renewable.

The pumps are designed to give self-regulation and high efficiency over a wide range, as will be seen from the two characteristic curves, figs. 28, 29.

The outputs of the pumps at a speed of 1,450 r.p.m. are given in the 'Table of Outputs,' and in connection with the horse-powers shown, the following allowances for contingencies should be made in fixing the power of the driving unit:

25% up to 3 B.H.P.	15% up to 10 B.H.P.	7½% up to 100 B.H.P.
20% „ „ 7 „	10% „ „ 50 „	5% above „ „

For speeds other than 1,450 r.p.m. the following rules approximately apply:

'Head' varies directly as the square of the speed; 'Capacity' varies directly as the speed B.H.P. varies directly as a product of R.P.M. and head.

TABLE OF OUTPUTS AT 1,450 R.P.M. OF STONE'S HIGH EFFICIENCY TURBINE PUMPS.

The outputs given in the above table are based on cold water, with a suction lift not exceeding 20 ft.

Pumps for Oils and Viscous Fluids.

The 'Stone-Paramor' Rotary Pump.

(J. Stone & Co., Ltd., Deptford, S.E. 14.)

This is a rotary pump specially designed for dealing with heavy fuel oils, lubricating oils, and all industrial viscous fluids. A special feature is that sliding contact between the inner and the outer rotor is reduced to a minimum, there being a high degree of rolling action.

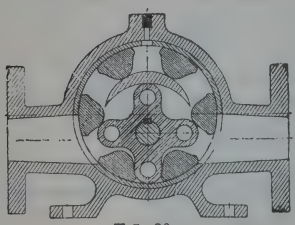

FIG. 30.

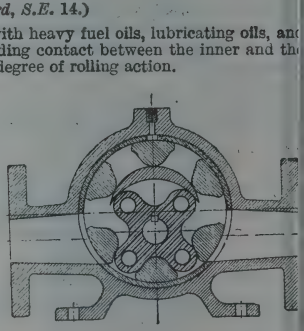

FIG. 31.

Figs. 30 and 31 show the rotors in two different positions. It will be observed that the shap of the teeth being cycloidal (as they are generated in accordance with the relative rolling actio between inner and outer rotors), the teeth of the inner rotor make continuous rolling contact wit the teeth or abutments of the outer rotor.

Particular attention has been given to the prevention of leakage in the suction and discharg when operating under heavy pressure. The figs. show that in any relative position of the tw rotating members this point is amply provided for, so that the volumetric efficiency of the pum is very high.

In all sizes provided with 3-in. branches and above, the pumps are fitted with ball bearing carried in end brackets, so that the inner rotor is always kept in a central position.

TABLE OF CAPACITIES.

Type.	Diameter of Branches.	Capacity. Tons per Hour.	R.P.M.	
			Min.	Max.
P.R.P. 1	1½ ins.	3	500	600
,, 2	2 ,,	7½	400	550

,, 16	15 ,,	450	100	150
,, 17	15 ,,	550	100	150

NOTE.—The capacities stated above represent the outputs of the pumps at minimum spe when dealing with heavy Mexican fuel oil.

The maximum speed stated can be employed on less viscous fluids and lubricating oils, but molasses, heavy oils, tar, etc., the lower speed should be selected.

When dealing with the lighter liquids the outputs of the pumps can be increased in proport to the speed.

The pumps are in use by many large oil companies for pumping fuel and lubricating oils, and also by many shipowners, as it is particularly adaptable for installing on board ship, also by large industrial concerns where viscous fluids have to be dealt with.

Scoop Wheels.

For raising large bodies of water through a small elevation the scoop wheel is very effective. At Amsterdam the canals are freshened by the drawing of water through them by 8 scoop wheels, discharging to the Zuyder Zee.

Their diameter is 8 m.; breadth, 3·25 m.; capacity, 300 m.³ each per minute; speed about 3 revolutions per minute. Floats inclined so that they enter water nearly horizontally, and leave nearly vertically. Height of lift, about 1·5 m.

The tendency to-day is to substitute the centrifugal pump for the scoop wheel even for small elevations.

Water Raising from Deep Wells by Compressed Air.

(1)

In this system, air under the necessary pressure, and of suitable volume, is admitted to the foot of a pipe immersed in the water to be lifted, as shown by fig. 32, p. 1340. By this means, alternate bands or plugs of air and water are formed in the water pipe or 'rising main,' and the air does not, as might perhaps have been anticipated, pass through the mass of water. The result of this is that the aggregate weight of the water in the rising main is insufficient to balance the column of water in the boring, and the pressure of the latter therefore produces an upward movement of the air and water column in the rising main. As the force lifting this column is the head of water at A, it follows that the height to which the water can be lifted depends upon the depth to which the pipe is immersed below the pumping level of the water in the boring: thus the higher the 'lift' required, the deeper must be the point at which the air is injected relatively to the normal water level therein, and consequently the height to which the water has to be raised determines the minimum depth to which the boring must be driven.

The following table shows the approximate horse-power required to compress 1 cubic foot of free air to different pressures per square inch:—

Locality.	Pressure in Pounds per Sq. Inch.	H.p. required to compress 1 Cub. Ft. of Air.	Locality.	Pressure in Pounds per Sq. Inch.	H.p. required to compress 1 Cub. Ft. of Air.
1. Solvay Works, Saaralben	176	0·434	5. Tunbridge Wells Waterworks	60	0·159
2. Brostowe Estate, near Friedheim	140	0·376	6. Sugar Factory, Glogan	45	0·145
3. Tunbridge Wells Waterworks	100	0·201	7. Yard Works, Zwickau	30	0·121
4. Ditto	80	0·189	8. Rossland Mines, B.C.	95	0·134

With regard to the quantity of air required to lift a given volume of water to any specified height, the following formula has been found to give correct results:—

x = cubic feet of free air per minute; A = gallons of water required per minute; B = 'lift' of water in feet;

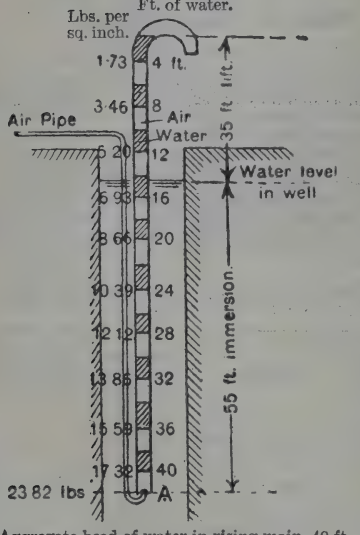
$$x = \frac{A \times B}{125}.$$

The velocity of the air should not exceed about 20 ft. per second.

In considering the design of the compressor, it is obviously important in the interests of economy to provide either 2-stage or 3-stage machines (with intercoolers) according to the amount of compression required; thus for pressures above 60 lbs. per square inch and up to 300 lbs. per square inch 2-stage machines are most suitable, and from this to 1,000 lbs. per square inch 3-stage machines are desirable. The cooling of the air is also of great importance in this respect, and care should be taken to start with an air supply at the lowest temperature obtainable.

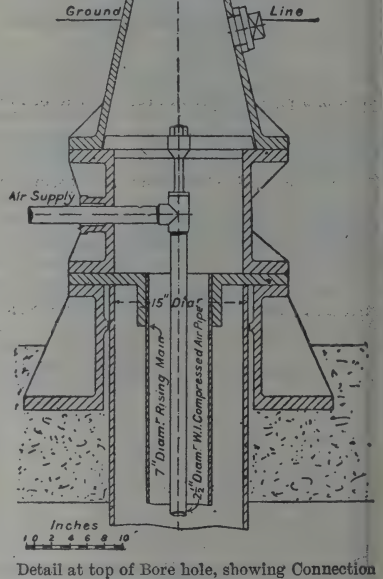
At Tunbridge Wells the compression is carried out in two stages, the first to a pressure of 25 lbs. per square inch, and the second, after intercooling, to the pressure required, which varies from 90 lbs. to 100 lbs. per square inch according to the depth of the water in the boring. The air is delivered into a large steel receiver situated in the engine-house, whence it is conveyed to the wells by means of a 4-inch cast-iron pipe. This main is formed of ordinary spigot and socket pipes with lead joints, which, however, shortly after starting the plant, showed signs of leakage adjacent to the receiver. This was traced to the expansion and contraction of the pipes due to the high temperature of the air, and was effectually prevented by fixing a cooler on the air pipe between the second stage compressor and the receiver.

There are two sets of engines and compressors, designed to deliver a sufficient volume of air to lift the desired quantity of water, if need be, over a standpipe 20 ft. high above ground level.



Aggregate head of water in rising main, 40 ft. = 17·32 lbs. per square inch.
Aggregate head in well = 55 ft. = 23·82 lbs. per square inch.

FIG. 32.



Detail at top of Bore hole, showing Connection of Air Supply.

FIG. 33.

The engines are compound, with cylinders 8 ins. and 12 ins. diameter respectively, the air-compressing cylinders being 10 ins. (first stage) and 6 ins. (second stage) diameter respectively. The stroke in each case is 14 ins. The air cylinders are water-jacketed at sides and covers. The clearance in the air cylinders does not exceed 1 per cent. of the capacity. The air is drawn from outside the building, and is carried in an earthenware pipe under the floor to the inlet valves, so that it enters the compressors at the lowest possible temperature.

An intercooler (between first and second stages of compressors), formed of a series of 'Row' tubes cooled by circulating water, is fixed outside the engine-house.

The boring is 350 ft. deep. The upper portion is lined with 15-inch steel tubes, and the lower portion (150 ft.) with steel perforated tubes, 13½ ins. diameter. The rest level of the water

is about 96 ft. from the surface, and the pumping level, when drawing at the rate of 32,000 gallons per hour, is about 120 ft. from the surface, but on the cessation of pumping the water resumes its rest level very rapidly.

The water pipe or rising main is 7 ins. diameter, and is carried to within a few feet of the bottom of the boring. The air pipe was originally 1½ ins. diameter, but was subsequently increased to 2½ ins. diameter, an alteration which reduced the air pressure required from 105 lbs. to 91 lbs. per square inch, the latter figure corresponding very closely to the head of water above the bottom of the air-pipe, and thus proving the loss by friction to be reduced to a minimum.

In a trial run of 10½ hours made soon after the plant was installed, an average of 31,402 gallons per hour was raised from this boring under a head of 133 ft., whereas an ordinary single-acting pump, such as could be fixed in a boring of this small diameter, would give no more than about 18,300 gallons per hour.

The most favourable result was obtained when the proportion of immersion of air pipe to lift of water was 3 to 1 at the start and 2·2 to 1 at the finish, the volume of air used per volume of water lifted being in the proportion of 2·69 to 1. The efficiency in this case was 36·8 per cent., calculated on the water raised proportionate to the indicated horse-power developed in steam-cylinders, and 46 per cent. calculated from the indicated horse-power shown by air-cylinder diagrams. No record of fuel consumption was made. If the proportion of immersion to lift is reduced the efficiency falls.

From a trial made with a much less immersion of air pipe than in the foregoing, and when the proportion of air used to water lifted was more than double that in the former case, the cost of fuel worked out at 1·073*d.* per 1,000 gallons for a maximum lift of 125 ft. 9 ins., the price of coal being 25*s.* 5*d.* per ton. (*W. H. Maxwell.*)

(2)

In order to enable the well to work successfully and economically, the pipe should be properly proportioned. When the pipe is too large, the water is apt to blow out in a spray and with great force, which is obviously very wasteful both of air and water. When the pipe is too small, the air is apt to rise to the surface of the water in small bubbles, and without producing the desired results. When the air pipe is outside of the water pipe, the proper relation between the diameters of the air and water pipes is as 1½ to 4, which gives a ratio of actual cross-sectional area of 6·24. When the air pipe is situated inside the water pipe, the same ratio of actual cross-sectional areas should obtain, and in this case the diameter of the water pipe is

$$D = \sqrt{\frac{a \times 6{\cdot}24 + A}{{\cdot}7854}},$$

in which a and A represent the actual internal and external areas of the air pipe. The proper areas of the air and water pipes, together with the required depth of submersion and the introduction of the air into the water pipe at the proper point, are the principal factors which determine the success of the air lift.

The water pipe should be submerged to a depth of 18 ins. for each foot lift above the lowest water level in the well; in other words, the best results are obtained when submersion $r = 1{\cdot}5$ the lift, the latter being measured from the lowest, or the working water level, as it is called.

When the well is being worked, the water level falls below the level reached, before water is pumped out. To illustrate the foregoing rule, suppose we wish to elevate water 25 ft. above the surface of the ground, and that when drilling, the well water is obtained at a depth of 40 ft. below the surface. The lift is now 40 ft. + 25 ft. = 65 ft. Applying the foregoing rule for depth of submersion, we have 65 ft. × 1·5 ft. = 97·5 ft., or practically 100 ft., thus giving a total height of 165 ft. from the point where the air enters the water pipe to the point of discharge. After drilling to a depth of 165 ft. − 25 ft. = 140 ft., we are ready to find the working water level in the well. First put the water and air pipes into the well; then drop a float attached to a string into the well. Pass the string over a pulley, and attach a weight to the free end. The weight should be just heavy enough to take up the slack in the string, and at the same time allow the float to descend with the water level as the latter is lowered by pumping. The distance the weight rises will indicate the depth of the working level below the level first obtained in the well, and the latter level should be employed when making calculations involving lift and depth of submersion. A very simple as well as convenient arrangement for measuring the fall of the water level in the well can be made as follows: Take a pulley whose circumference is twelve times the circumference of the shaft upon which the pulley is mounted, then wind the float string around

the pulley, and fasten another string to the shaft, so that it will be wound on the shaft as the float string unwinds from the pulley. It will be seen that this arrangement reduces the travel of the string on the shaft to a convenient length, and one that can easily be measured. Suppose the water level in the well falls 10 ft. The corresponding additional depth of submersion will be 10 ft. × 1·5 ft. = 15 ft., and if the well is not deep enough it should be drilled to a sufficient depth to permit the increased depth of submersion to be obtained, and this is done in order to make the total depth of submersion equal to 1½ times the lift, which proportion, as has been pointed out, is necessary for the best results. If it is not practicable to increase the depth of submersion after finding the working level, the height of the lift may be decreased a corresponding amount; otherwise the efficiency of the lift will be to some extent affected. If the well had been drilled deeper than necessary at the outstart, the increased depth of submersion could readily be obtained by simply lowering the pipes to the required depth. It will be seen that the lower water level in the well also determines the necessary change in the point at which the air should enter the water pipe. With a fall of 10 ft., when pumping, the air should enter the water pipe at from 38 ins. to 40 ins. from the lower end of the pipe; with a fall of 5 ft. the air should enter at from 24 ins. to 26 ins. from the lower end of the water pipe, and with a fall of from 1 ft. to 3 ft. it should enter at a point 18 ins. to 20 ins. from the lower end of the pipe. For other distances the same ratio may be used. A well put down to the depth previously determined and fitted with pipes of the sizes indicated by the rule, can be cemented over, and buildings erected over it, without fear of trouble, because the well will need no further attention, and all that is required is simply to supply it with air as long as the pipes last. A number of wells can, of course, be operated from the same compressor. The necessary machinery can be located in the engine-room, or in any convenient place, and the air pipes run to the different points of distribution.

It is estimated that 1 cub. ft. of air will raise 1 gallon of water, but in wells that are properly proportioned there will be a saving over the amount of from 40 to 47 per cent.; that is to say, the air used will be 60 per cent. of the above estimate as the maximum, and 52 per cent. as the minimum. To illustrate the application of the rule for volume of air required, if we wish to raise 100 gallons of water, we shall need 60 cub. ft. of air as the maximum, and 52 cub. ft. of air as the minimum, the required volume carrying from the maximum to the minimum according to the conditions in each individual case. The average air pressure is 60 lbs. per square inch. When starting to raise water, it requires a somewhat higher pressure, because there is a solid body of water from the surface in the well to the point at which the air enters the water pipe, and this column of water has to be moved by the first discharge of air. When the well has reached its normal working condition, the water pipe will contain a number of short columns of air and short columns of water. These short columns of air and water are discharged alternately, and in the pipe they form a continuous chain, the intermittent discharge continuing as long as the proper amount of air is supplied, and as long as there remains water to be pumped.

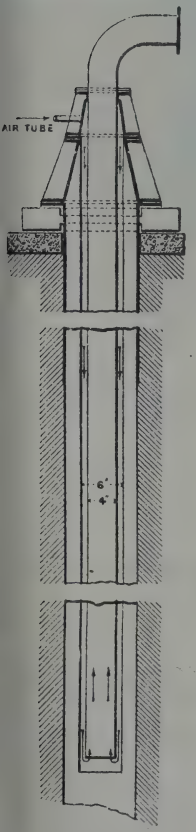

FIG. 34.

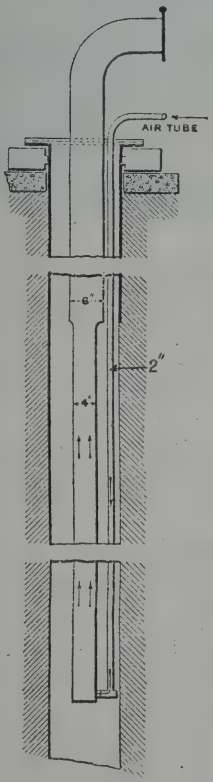

FIG. 35.

(G. C. H. Fredrich.)

At the works of the United Alkali Company, Limited, at Preesall,* a well 450 ft. in depth and 12 ins. in diameter at the bottom is fitted, as shown in figs. 34, 35, with a lining tube going down to the rock-head, and an air tube 6 ins. in diameter, with a delivery tube 4 ins. in diameter inside it, the effective cross-sectional area of the air tube being thus the area of the annulus formed between it and the delivery tube. For working this well a small Ingersoll-Sergeant air compressor was (1906) used.

In another well the delivery and air pipes are arranged on a different plan. In this case the air pipe passes down the well outside the delivery pipe and is connected to it at the bottom, as shown in fig. 35; the air-compressing plant consists (1906) of an Ingersoll-Sergeant cross-compound air compressor, having both the air and the steam cylinders compounded. The speed is regulated by a governor in the usual manner, and also by the pressure of the air as it leaves the high-pressure air cylinder. The air cylinders are water-jacketed, and the air from the low-pressure air cylinder is delivered to an inter-cooler from which it passes to the high-pressure air cylinder. The air suction valves are carried on the piston, the air passing into the piston through a hollow tail-rod working through a stuffing box and gland on the end of the cylinder, and the delivery valves are controlled by suitable spiral springs. The steam cylinders are 20 ins. and 32 ins. in diameter, and the air cylinders 28·25 ins. and 16·75 ins. in diameter, the stroke being 24 ins. The percentage of clearance in the air cylinders is very small. The air is compressed to 35 lbs. per sq. in. in the low-pressure cylinder, and in the high-pressure cylinder to a pressure ranging between 80 lbs. and

* J. Kelly (*Proceedings of the Institution of Civil Engineers*, vol. clxiii. May 1906).

120 lbs. per sq. in., according to the depth of submersion of the delivery pipes in the well or wells under operation.

Mr. Rix, in a paper read before the Technical Society of San Francisco, concludes that, with lifts not exceeding 20 ft., 1·5 cub. ft. of air will be required for each cub. ft. of water raised; for lifts of 20 ft. to 50 ft., 2 to 3 cub. ft.; and for lifts of 50 ft. to 100 ft., 3 to 4 cub. ft. will be required. He limits the velocity of the water entering the pipes to 4 to 8 ft. per second.

Air-lift pumping systems are not advisable where the submergence is below 35 per cent., and the best condition for this type of pump is from 45 per cent. to 60 per cent. submergence. By submergence is meant the ratio of the depth of the mixing chamber below the pumping water level to the total height pumped.

With air-lift pumps the hotter the liquid to be pumped the higher will be the efficiency of the pump. It has been shown by Prof. Randall that an efficiency of 100 per cent. is possible under certain conditions when pumping water at 200 deg. Fah.

SECTION XXV

PART III

THE DEVELOPMENT OF WATER-POWER.

(Partly contributed by Arthur Surveyer, D.Eng., M.E.I.C., M.Inst.C.E.)

WATER-POWER.

The theoretical power or effective energy of a fall of water, in ft.-lbs. per min., is equal to the weight in lbs. of the volume of water flowing per min. over the fall, multiplied by the vertical height of the fall in ft.

$$\text{H.P.} = \frac{Q \times h \times W}{550} = \frac{Q \times h \times 62{\cdot}5}{550} = \frac{Q \times h}{8{\cdot}8},$$

where,

Q = discharge in cub. ft. per sec.; W = weight of 1 cub. ft. of water = 62·5 lbs.; h = net head or net fall of water in ft.; H.P. = horse-power (33,000 ft.-lbs. per min. or 550 ft.-lbs. per sec.).

Thus 1 cu. ft. of water per sec. falling through a head of 10 ft. will develop theoretically 1·134 h.p.

For practical purposes, and in order to take into account the losses in the water-wheels, it is better to adopt the following formula, which is based on a water-wheel efficiency of 80 per cent.,

$$\text{Practical H.P.} = Q \times h \div 11.$$

An efficiency of 80 per cent. is now attained even in the medium-priced wheels, and 90 per cent. is frequently reached in the high-priced wheels. Assuming an efficiency of 88 per cent., then

$$\text{Practical H.P.} = Q \times h \div 10.$$

10 tons of water (about 320 cu. ft.) falling 100 ft. develops the energy equivalent to that which can be produced through the burning of one pound of coal. That is, 10 tons, or 20,000 lbs., falling 100 ft., will develop 2,000,000 ft.-lbs. Dividing this by 778 gives 2,570 B.Th.U. of energy. Assuming a hydraulic turbine efficiency of 92 per cent., which is a fair average for a modern hydraulic turbine, the energy actually developed from this water is about 2,370 B.Th.U. This corresponds to the energy made available by the combustion of coal having a heating value of 13,000 B.Th.U. per lb. with an over-all plant thermal efficiency of approximately 18 per cent., which is perhaps fairly representative of good central-station practice although not equal to the best, which approaches 25 per cent.

Tide-Power.

A horse-power for a day of ten hours would require something like 120 tons of water falling from a height of 100 ft., so that a 500 h.p. factory, say, would need 60,000 tons of water at a 100-foot head. On the basis of 36 cub. ft. of water to the ton, there would thus be over 2,000,000 cub. ft. of water, and this would make a fair-sized pond, say, about 1,000 ft. long, 200 ft. wide, and 10 ft. deep.

The possibilities of tidal power, if it can be developed commercially, are very great.

In Great Britain the highest tides are found in the estuary of the Severn, the mean range of the spring tides at Chepstow being 42 ft., and of the neap tides 21 ft. In France the maximum range occurs at St. Malo, where it amounts to 42·5 ft. at spring tides, and about 18 ft. at neap tides. The tidal range in the Dee is 26 ft. at springs, and 12 ft. at neaps, while the mean range of spring tides around the coast of Great Britain is 16·4 ft., and of neap tides 8·6 ft.

Assuming a mean tidal range of only 20 ft. at springs, and 10 ft. at neaps, and adopting the single-basin method of development with operation on both rising and falling tides, each square mile of basin area would be capable, without storage, of giving an average daily output of approximately 110,000 h.p.-hours. In such an estuary as the Severn, where an area of 20 square miles could readily be utilised with a spring tidal range of 42 ft., the average daily output, without storage, would be approximately 10,000,000 h.p.-hours.

(*'Nature,'* June 3, 1920.)

TABLE SHOWING PRACTICAL HORSE-POWERS CORRESPONDING TO HEADS, IN FEET, AND CUBIC FEET USED PER MINUTE, OF WATER.

(1 cu. ft. per min. = 1·7 cu. metres per hr. 1 cu. metre per hr. = 0·59 cu. ft. per min.)

The practical horse-power is taken at 80 per cent. of the theoretical.

GENERAL FEATURES OF A WATER-POWER DEVELOPMENT.

Although the lay-out of hydraulic plants changes with every water-power site, there are certain features which are generally found in all developments, and which can be described as follows :

1. The dam, which impounds the water, regulates the level of the upper pool, and directs the water towards the water wheels.

2. The head gates, which control the supply of water, and by means of racks permit the removal from the water supply of injurious floating and suspended matter.

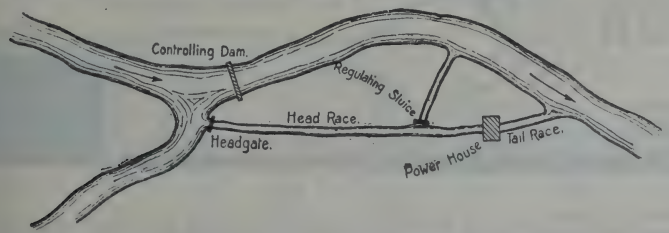

FIG. 1.—Typical General Arrangement of Hydraulic Development.

3. The head race, flume or penstock, which carries the water to the wheels.
4. The power house, which contains the hydraulic machinery.
5. The water wheels, which transform the hydraulic energy.

6. The draft tube, and the tail race, which discharge the water used in the power house into the river.

In some plants the power house forms a part of the dam, and the water is delivered to the wheels without passing through a canal or penstock and discharged back into the river directly through the draft tubes.

Fig. 1 shows a rather complicated lay-out, with a regulating canal for the head race. The regulation of the level of the upper pool is obtained either by a regulating weir, sluices in the dam, or a movable dam.

In approaching the study of any water-power site, the two first things to be determined are the head of water available at all times and the characteristic flow of the river. It is not economical to install machinery which can utilise only the minimum flow of the river, and it is considered good practice to build a plant capable of using the *characteristic flow* of the river, which can be defined as the available dependable flow during at least nine months of a low year.

The available head is determined by levelling and by the daily reading of gauges located in the upper and lower pools of the proposed development.

The *characteristic flow* is found by a series of discharge measurements combined with the daily reading of gauges extending over as long a period as economically possible.

Characteristics of the Flow of Rivers.

The discharge of rivers varies with the precipitation on their drainage basin, the evaporation, the volume of the run off, and the rapidity with which the underground as well as the surface waters reach the river.

The study of drainage basins includes the study of the discharge of streams, of the relations between the stream discharge and the water precipitation, on the drainage basin, on the flood discharges and the rains which cause them, etc.

Discharge of Rivers.

Given a river with an unchangeable bed, there is a fixed relation between the level of this river at a given point and its discharge at that point. Except in the cases of rivers carrying and depositing large quantities of gravel and sand, it is fair to assume that the bed does not change. The discharge curve of a river is obtained from actual measurements, plotted at a suitable scale on cross-section paper. The gauge heights are taken as ordinates and the discharge as abscissæ. The several points thus plotted are connected together by a curve so drawn that the algebraic sum of the squares of the errors is minimum. This curve is a parabola of the form $Q=a+bh+ch^2$. It is often found advisable to develop the discharge equation of a river, and in order to do so the parameters a, b, c can be calculated in each case, from actual measurements, by the method of the least squares.

Measurement of Quantity of Water Flowing in a Stream.

Weir Measurement.

(1)

Rectangular Notch Method.

For small streams a weir dam is used, as shown by fig. 2, consisting of a board long enough to reach across the stream with either end set in the bank. A notch is cut in the board, deep enough

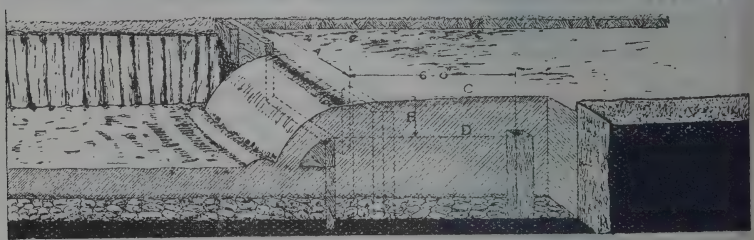

Fig. 2.

to pass all the water, and long enough to reach about two-thirds A, across the stream. The bottom and ends of the notch, D, in the board should be bevelled on the down stream side, leaving the upper edge sharp. The stake, E, should be driven in the bottom of the stream, several feet from the board, on a level with the edge of the notch D. When the water has reached its greatest depth, a measurement, B, can be made of the depth of water over the stake E. The dotted line C represents the top of the running water, and the distance between this line or level of water and the top of the stake gives the true depth or spill over the weir board.

The surface of water below the board should be at least 10 inches lower than the notch D. A part of the stream should be selected where the water can approach the notch quietly.

The weir described above is called a *contracted weir* ; if the sides of the notch are continuous with the sides of the channel it is a *suppressed weir*, or a *weir without end contractions*.

According to the different cases we have the following formulæ giving the discharge in cub. ft. per sec. :

With end contractions and a velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{(H+1{\cdot}44h)^3}\ ;$$

where water has no velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{H^3}$$

without end contractions but with velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{(H+4/3\ h)^3}\ ;$$

where water has no velocity of approach,

$$Q = 5{\cdot}347\ CL\ \sqrt{H^3}\ ;$$

in which

L = Length of weir in ft. ;
H = Head in ft. ;
V = Velocity of approach in ft. per sec. ;
h = Head equivalent of velocity of approach = 0·01555 V^2 ;
C = Coefficient of discharge ;
Q = Discharge in cub. ft. per sec.

The readings obtained at the weir dam are used with the weir table, thus :—

The figures 1, 2, 3, etc., in the first vertical column of the weir table are the inches depth of water running over the notch of weir. The top horizontal line shows fractional parts of an inch ; the body of the table shows the cubic feet and the fractional parts of a cubic foot that will pass each minute, for each inch and fractional inch depth of water in notch. Each of these results is for one inch only of weir, as follows :—

EXAMPLE.—Suppose the notch in board is 20 inches wide and the water at the stake E 5½ inches deep. Take the column containing figure 5 and the one containing figure ½, and the square where they meet contains 5·18 cubic feet. This is the quantity of water passing for each inch in width ; but the weir is 20 inches wide, therefore this result, multiplied by 20, gives 103·6 cubic feet per minute. The same method applies to any depth from one to 25 inches, or any width.

The foregoing only applies in cases where the weir or notch is without end contractions, and discharging from still water.

(2)

'V'-Notch Method.

In this method a 'V'-shaped notch, fig. 3, is cut in the sill board, this notch being of sufficient size to allow the full volume of water to discharge through it. When the flow is steady, then

$$Q = \frac{4}{15} kwh \sqrt{2gh}, \text{ cubic feet } \textit{per second},$$

w, h, and g being in *feet*.

The value of k varies from ·59 to ·62, according to the angle α, being ·59 for a right angle (90°).

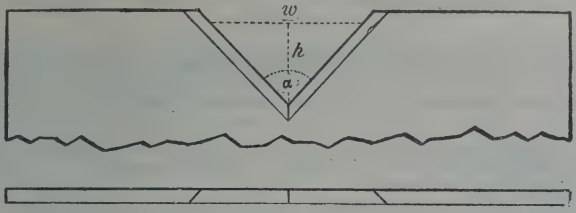

FIG. 3.

When α is a right angle, then $w = 2h$, and formula becomes

$$Q = \cdot 3h^2\sqrt{h}, \text{ cubic feet } \textit{per minute},$$

h being in *inches*.

The advantage of the 'V'-notch method is that the ratio of the wetted perimeter of the notch to the area of outflow is the same for any value of h.

A series of 'V'-notches may be cut in the sill-board if the flow of water is great; these notches should be of equal size, and their apexes should be exactly in line, and this line should be exactly horizontal.

When a series of 'V' notches is used, there is a certain amount of mutual interference between the several jets, and in order to get complete immunity from this the notches should be seven times the head apart. If the notches are $3\frac{1}{2}$ times the head apart, the error may be, but would not exceed, ·5 per cent. (*H. S. Rowell.* '*Engineering*,' *May* 2, 1913.)

WEIR TABLE FOR RIGHT-ANGLED 'V'-NOTCH (FROM ONE INCH TO THIRTY INCHES DEEP) GAUGING, GIVING DISCHARGE (Q) IN CUB. FT. PER MIN. FORMULA :—$Q = \cdot 3h^2\sqrt{h}$.

FLOW OF WATER OVER SHARP-EDGED NOTCHES AND WEIRS.

(1) Flow over a triangular notch.

$$Q = 2{\cdot}48nH^{2{\cdot}47}.$$

Q = cub. ft. per sec.; n = tangent of half-included angle of notch; H = head in feet.

(2) Flow over any trapezoidal notch = flow over a rectangular weir of equal length with two end contractions, plus the flow through a triangular notch of corresponding angle.

(3) Flow over a rectangular weir with end contractions varies as—

$$Q = 3{\cdot}10\,L^{1{\cdot}02}\,H^{1{\cdot}47},$$

for all weirs up to at least 19 ft., and for head up to half length of weir, provided depth of post below sill of weir is not less than twice the head. L = length in feet.

General law for trapezoidal weirs:

$$Q = 3{\cdot}10\,L^{1{\cdot}02}\,H^{1{\cdot}47} + 2{\cdot}48nH^{2{\cdot}47}.$$

Sluice Measurement.

(*Contributed by J. F. Maryon, M.I.Mech.E.*)

Raise the sluice gate, taking care that the level of the water above the sluice gate is constant, and take the three measurements shown, D being the height from the bottom of the sluice gate to the sill over which the water is flowing, W the width of the opening, and H the distance from

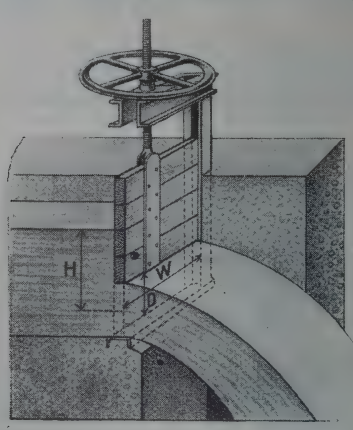

FIG. 4.

the surface of the water above the sluice gate, to a point half-way between the bottom of the sluice gate and the sill. Having obtained these figures in feet, the quantity of water passing in cubic feet per minute is as follows:—

$$Q = W \times D \times 8\sqrt{H} \times 42.$$

Measuring Open Streams.

(*Contributed by J. F. Maryon, M.I.Mech.E.*)

To measure the discharge of a stream it is necessary to obtain by soundings an accurate cross-section of the river at the point of observation. This section is subdivided into a certain number

of sections, A, B, C, D, E (fig. 5), and the mean velocity of flow accurately determined for each sub-section. We have then the relation $Q=AV$; where Q=discharge in cub. ft. per sec., A=total area in sq. ins., and V=mean velocity in ft. per sec., throughout the section.

$$Q=q_1+q_2+q_3+ \ldots = A_1V_1+A_2V_2+A_3V_3+ \ldots$$

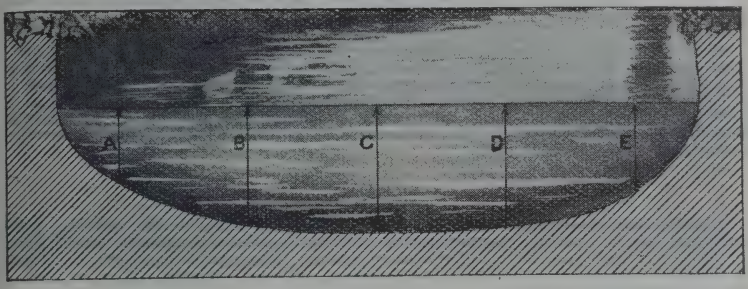

FIG. 5.

The mean velocity occurs at about 0·6 of the depth of a stream, but the mean between the velocities observed at 0·2 and at 0·8 of the depth will also give the mean velocity for the total depth.

MEASUREMENT WITH FLOATS.

In order to measure the velocity of the current in the different sections by means of floats it is necessary to lay out on the shore two parallel ranges perpendicular to the general direction of the current and distant from each other by 200 or 300 ft.

A series of floats are afterwards dropped at a certain distance above the upstream range and their course determined either by transits set up on the shore, or by sextants from a boat kept a few feet distant from each float during its downstream travel.

The passage of each float in line with the upstream and downstream range is recorded with a stopwatch and the mean velocity of the float throughout the distance calculated.

(a) Measurement with Rod Floats.

If a rod float is made to float vertically at a section of the stream so that its lower end is not more than a foot or so above the bed of the river at that point, such a float will be carried downstream by the current at a rate corresponding approximately to the mean velocity of the current at the point considered. It is not always practically possible to fulfil this condition, and even with a complete set of hollow galvanised iron rod floats, which can be sunk at will by loading them with shot, it is found necessary to correct the observed velocity and to reduce it to the mean velocity by using the following formula, due to Francis:

$$V_m = V_r\,(1-0{\cdot}116\,(\sqrt{d}-x)),$$

where

V_m = mean velocity for the vertical section considered;

V_r = observed velocity of the rod float;

$$d = \frac{\text{distance between bottom of rod and river bottom}}{\text{depth of river}};$$

x is a function of $\frac{l}{d}$, l being the length of the rod and d the depth of the water.

The following shows the values of x corresponding to various values of $\frac{l}{d}$:

$\frac{l}{d}$	0·9	0·8	0·7	0·6	0·5
x	0·10	0·05	0·00	−00·5	−0·10

When $\frac{l}{d}$ = 0·9 or more, the formula is that given by Francis:

$$V_m = V_r\,(1-0{\cdot}116\,(\sqrt{D}-0{\cdot}1)).$$

(b) Measurement with Submerged Floats.

It is possible by means of a surface float connected by a string to a submerged float held at a depth equal to about 0·6 of the depth of the stream at that point, to obtain directly without correction the mean velocity in a section. The surface float is generally made very flat so as not to be affected by the wind, and the sub-surface float is generally composed of two pieces of galvanised plate placed cross-wise and terminated at their upper end by hollow tubes in order to give the submerged float the necessary buoyancy.

Measurement by Meters.

The current meters used to measure the velocity of water consist in a wheel of some form so constructed that it is made to revolve by the impact of flowing water, the number of revolutions of this wheel being either recorded, or indicated to the observer. The relation between the velocity of the moving water and the revolutions of the wheel is determined by rating each meter.

Meter Rating.

To rate a meter it is necessary to drive it through still water at a uniform velocity and over a given distance. The distance being known and the time taken to cover it as well as the number of revolutions being noted, it is possible to determine the velocity per second and the number of revolutions per second for this velocity. The experiment must be made at varying speed of translation, so that a complete rating curve can be obtained for each instrument. This curve in all meters is practically a straight line. Meters are not generally reliable for the measurement of velocities of less than 0·3 ft. per sec.

(See also Section XXVII., p. 1497.)

DAMS.

Dams are constructions placed across a stream to impound water, to raise the level of the water upstream, or to divert a part or the whole of the river flow towards the water wheels either by means of a head-race, flumes, or pipes under pressure. Dams can be built with earth, loose stones, timber, masonry, concrete, reinforced concrete, and even with steel. They are fixed or movable according to the needs.

Dams can be built with their crest above the level of the highest waters, and provided with sluiceways, or they can be designed with spillways allowing the water to flow over their crest.

Earth Dams.

Earth dams (fig. 6) can, on account of their large base, be built on less resisting foundations than those constructed of other materials provided of course that the bed of the river is impermeable. The section of these dams varies according to local circumstances, and with the materials used. In general the upstream slope is either 3 to 1 or 2 to 1, and the downstream slope about 2 to 1. The centre part of earth dams is often constituted by a core of impermeable material, generally a mixture of sand and clay (two-thirds of sand and one-third of clay). Sometimes this core puddle is replaced by a concrete core wall driven into the bed of the river to an impermeable strata. In designing these concrete core walls, it is necessary to make them strong enough to resist the stresses induced by the settlement of the earth embankment.

Rock-Fill Dams.

Rock-fill dams (fig. 7) are also used on uncertain foundations, because the loose stones tumble into place when erosions take place. They are generally given a fair width at the top, with slopes varying between 1 in 1 and 2 in 1; they have the disadvantage of not being water-tight, although they can be made practically so by placing on the upstream slope an impermeable layer of sand and clay. It is not advisable to allow the water to discharge over these dams, and like the earth dams they must be provided with sluiceways and waste gates.

Timber Dams.

Timber dams (fig. 8) are either hollow or filled; the hollow dam consists of a wooden frame covered by an apron on the upstream and on the downstream side and held in place by the weight of water. The filled dams or crib dams consist of boxes made of large pieces of timber bolted together and filled with loose stones. These dams have generally a nearly vertical downstream face and an upstream face sloping 1 to 1 or 2 to 1; they are held in place partly by their own weight and partly by the weight of the water on top of them. They can be used either on solid foundations or on medium foundations; in the latter case, the upstream and downstream toes should be protected by loose stone, in order to prevent erosion.

Masonry and Concrete Dams.

These dams are used principally when the foundation is rock or hard pan, and are generally built with a practically vertical upstream face and a downstream slope of 1 to 1.

Masonry is used chiefly in the construction of storage dams provided with sluiceways, but concrete can be used either for storage dams or spillways.

Reinforced Concrete Dams.

The characteristics of these dams (fig. 9) are that they are formed by a series of vertical buttresses upon which is placed a reinforced concrete deck, the buttresses being also connected, underneath the deck, by reinforced concrete beams or slabs. These dams can be used either on a rock foundation or on uncertain ground; in the latter case they are generally built over a reinforced concrete mattress distributing the pressure over the foundation. Their upstream face is inclined at an angle of 45° and the buttresses are practically vertical on the downstream side. In the case of a spillway, the downstream side is formed in the same manner as the upstream side, by a reinforced concrete apron of the shape required by the quantity of water which is expected to flow over the crest. These dams have the advantage of requiring much less material than the

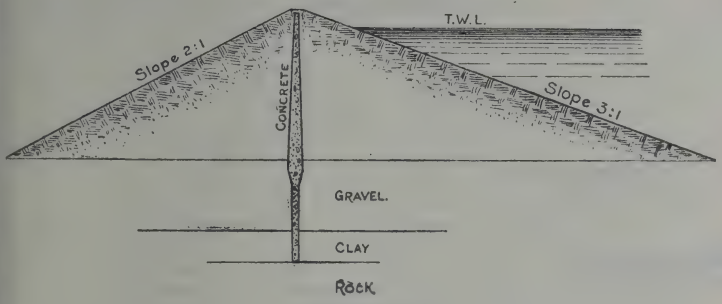

FIG. 6.—Earth Dam.

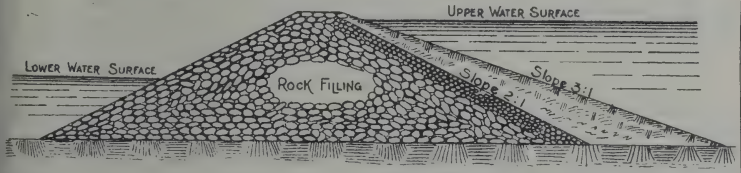

FIG. 7.—Rock-fill Dam.

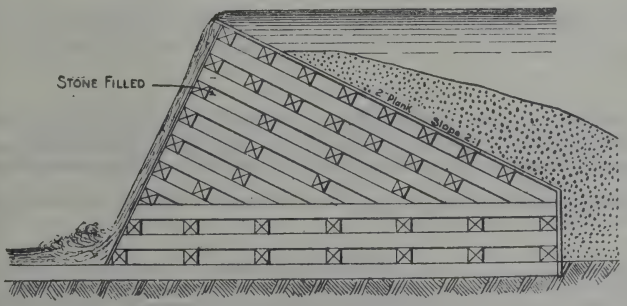

FIG. 8.—Timber Dam.

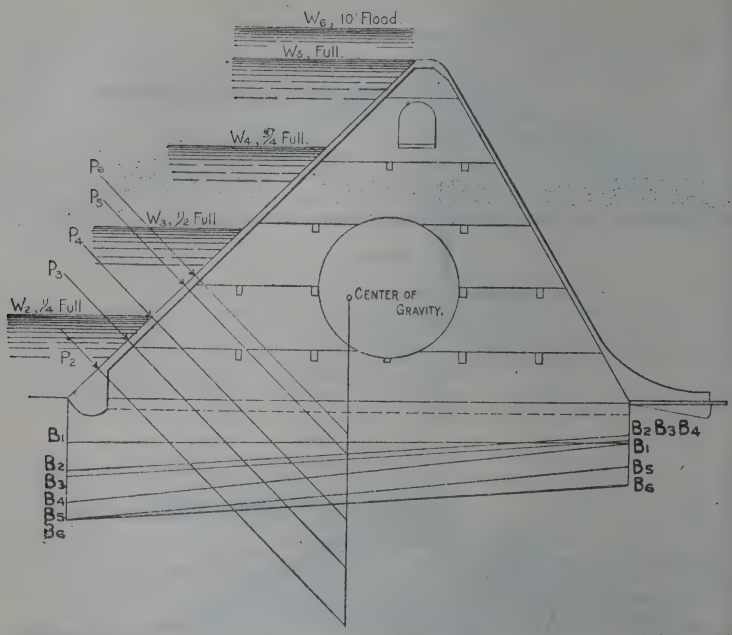

FIG. 9.—Reinforced Concrete Dam.

gravity dams, and are consequently used in places where transportation is difficult. Another advantage also is that their upstream face being inclined at 45° they resist better than the vertical face dams the ice pressures which, on account of their uncertainty, are always difficult to provide for.

Stability of Dams.

When dams are built on rock or solid foundations they can be built up from the bed of the river. If the bed is in hard pan the construction must be started below the bed of the river, and if the bed is composed of sand or gravel the dam generally rests on piles driven into the soil.

CONDITIONS OF STABILITY.

1. The weight of the dam must be sufficient to resist the water thrust tending to overturn it.
2. The dam must be so designed that there is no danger of its sliding upon its base.
3. The pressure on the downstream toe of the dam caused by the overturning moment must not exceed the resistance in compression of either the masonry or the foundations upon which it rests.
4. The resultant of all forces must be such that the upstream face of the dam is not in tension, but rather subject to a compressive stress.

Design of Dams.

Every design of dam must, of course, be tested for the foregoing different conditions, but the following rule will be found useful in arriving at a first tentative determination of the section.

Let h (fig. 10) be the greatest depth of water in the proposed reservoir at the dam. The width of the base B′C′ can be taken as equal to the height h or AB′, and the theoretical section of the dam would then be represented by the triangle B′AC′. In practice, however, it is necessary to give to the crest a certain thickness which can be taken as equal to one-tenth of the height. The portion AH above the highest water in the reservoir is generally made from 3 to 10 ft. When

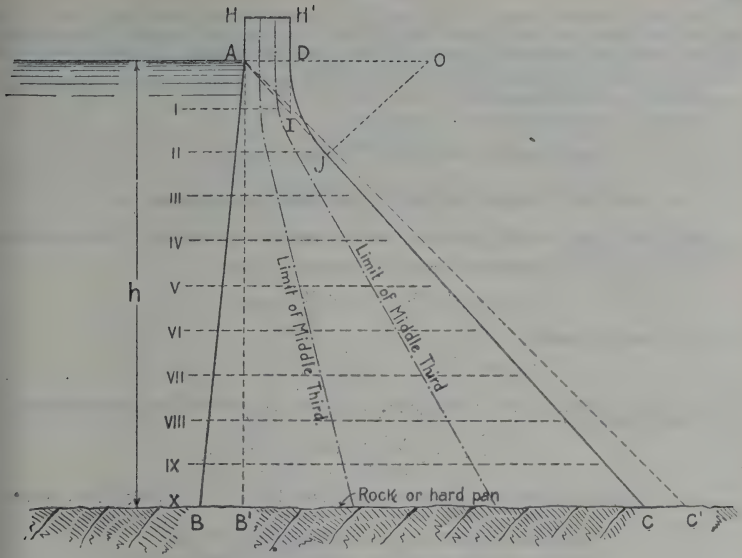

FIG. 10.—Masonry or Concrete Storage Dam.

the dam is very high it is difficult to build the upstream face vertical; it is preferable to give it a batter of 0·10 to 0·20. As it is not necessary to give to the base a greater width than the total height AB′, the point C′ is therefore brought back to C over a distance equal to BB′.

The downstream face is curved at the upper part into an arc tangent to the vertical H′I at D and to the inclined line AC at J. The section of the dam is therefore represented by the polygon BAHH′DJC.

DESIGN OF SPILLWAY DAMS.

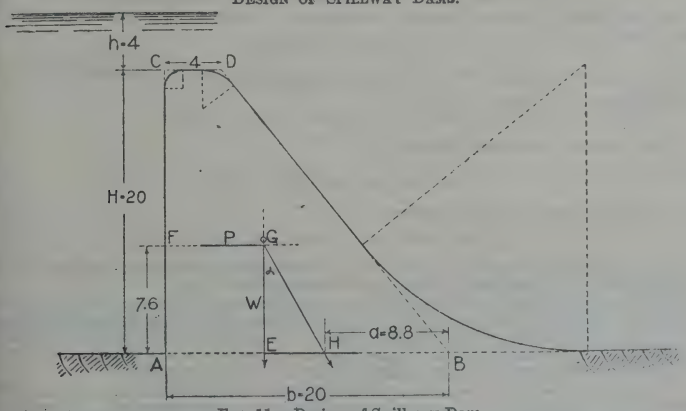

FIG. 11.—Design of Spillway Dam.

Spillway dams, or weir dams, are designed so as to allow the water to flow over their crest. The two first points to decide before beginning the design of such a dam are the elevation of the crest of the dam and the elevation of the highest possible flood.

Assuming that the elevation of the crest is 20 ft. above the bed of the river, and that the greatest flow of the river can be passed over the dam when the water level is 4 ft. above its crest, we can now proceed to design a plain concrete dam to meet these conditions, fulfilling at the same time the requirements as to stability enumerated above.

The width of the crest OD (fig. 11) can be taken as 0·2 of the height of the dam, and the width of the base b equal to the height H.

Referring to the figure we have the following:

$$A = \text{area of section of dam} = \frac{4+20}{2} \times 20 = 240 \text{ sq. ft.};$$

w = weight of 1 cub. ft. of concrete = 130 lbs.;
W = weight of section of dam 1 ft. wide = $240 \times 130 = 31{,}200$ lbs.

This force W acts vertically through the centre of gravity of the section G, whose position is determined graphically.

The water pressure P tending to overturn the dam has for value

$$P = 62{\cdot}5 \times \frac{(H+h)^2 - h^2}{2} = 62{\cdot}5 \frac{H}{2}(H+2h),$$

and in the case in question,

$$P = 62{\cdot}5 \times \frac{20}{2}(20+2\times 4) = 17{,}500 \text{ lbs.}$$

This force P acts horizontally, and is applied at a height AF above the bed of the river given by the following formula:

$$AF = \frac{H}{3} \cdot \frac{H+3h}{H+2h} = \frac{20}{3} \times \frac{20+12}{20+8} = 7{\cdot}6.$$

Taking the moments about the downstream toe of the dam B we have the following results:

$$\text{Resisting moment} = W \times EB = 31{,}300 \times 13 = 405{,}600 \text{ ft. lbs.}$$
$$\text{Overturning moment} = P \times AF = 17{,}500 \times 7{\cdot}6 = 133{,}000 \text{ ft. lbs.}$$
$$\text{Factor of safety} = \frac{\text{Resisting moment}}{\text{Overturning moment}} = \frac{405{,}600}{133{,}000} = 3{\cdot}05.$$

A factor of safety of 3 is considered sufficient to fulfil the first condition of stability.

The second condition is that there should be no danger of the dam sliding upon its base; this condition is fulfilled if we have the following inequality:

$$\text{Weight of dam} \times \text{coefficient of friction} > \text{Total water pressure.}$$

The coefficient of friction of masonry on masonry, or masonry or concrete on rock, is 0·7, so that we have

$$31{,}200 \times 0{\cdot}7 > 17{,}500.$$

The resultant R of the forces P and W can be found graphically or algebraically by the following equation:

$$R = \sqrt{W^2 + P^2} = \sqrt{31{,}200^2 + 17{,}500^2} = 35{,}770.$$

Its direction can be found by the equation

$$\tan \alpha^\circ = \frac{P}{W} = \frac{17{,}500}{31{,}200} = 0{\cdot}56;$$

and the point of application H found thus

$$EH = AF \tan \alpha^\circ = 0{\cdot}56 \times 7{\cdot}6 = 4{\cdot}26.$$

This point of application H must fall within the middle third of the base; this condition must be fulfilled whether the reservoir created by the dam is full or empty.

It is advisable to round up the dam at the upstream corner C to prevent chipping by logs or floating ice. It is also advisable to give to the downstream face a form resembling as much as possible the probable curve of the overfalling water. Corner D should therefore be rounded up and a concave curve built at B, so as to carry the water x away horizontally and without impact. The foregoing method can, of course, be used also in the case of storage dams.

When the proposed dam is over 30 or 40 ft. it is better to subdivide it into a certain number of sections and to test each block separately according to the method described; the resultant in each case must fall within the limits of the middle third. In the example given it has been assumed that there was no upward water pressure at the base; when infiltration and under pressure must be provided for, this new force is subtracted from the weight and combined with it before calculating the resisting moment.

Head Gates.

Head gates (fig. 12) are placed at the entrance of the head race, in order to permit the emptying of the canal and pipes in case of repairs, and in order to be able to stop quickly the admission of water in case of accident to the canal, flumes, pipes, or water wheels.

The head gates are, of course, built differently, according to the size of the opening they have to close.

Head gates for a canal consist of wooden or steel gates moving between concrete, masonry, or crib piers. The weight of the heavy gates is generally partly balanced by a counter weight, and they are raised and lowered by electric or hydraulic motor. The smaller gates are moved by hand with the help of a mechanical hoist.

The piers must be designed to withstand a pressure equal to the total head of water multiplied

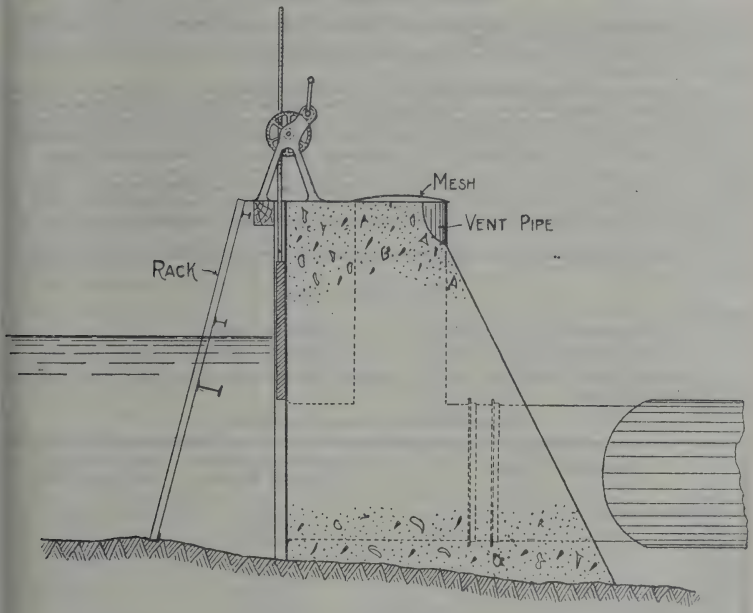

FIG. 12.—Head Gate and Rack.

by the distance between the centres of two adjoining openings. The factor of safety must be at least 3.

When pipes are used to carry the water to the turbines they are generally protected by a concrete head wall designed to resist the full hydrostatic pressure. The gates in this case are much smaller, and are operated by hand.

The force necessary to raise the gate can be calculated as follows:—The total weight of gate in water plus the total water pressure on the gate must be multiplied by a coefficient of friction which varies according to the materials used. To this weight should be added the weights represented by the mechanical losses in the transmission of power, and the grand total increased by about 13 per cent. in order to provide for the extra force necessary to start the gate.

Racks.

Racks are usually made of flat bars having sections from $\frac{5}{16}$ in. by 1 in., to $\frac{1}{2}$ in. by $3\frac{1}{2}$ ins., held together by bolts and separators. These racks may be either of large or small spacing, the former being those in which the bars are from $1\frac{1}{2}$ ins. to 4 ins. apart, and the latter where the bars are from $\frac{1}{2}$ in. to $1\frac{1}{2}$ ins. apart. The spacing is determined by the cross section of the openings of the distributor and runner buckets of the water wheels.

The racks are generally placed at an angle varying from 45° to 60° with the vertical; there should always be an operating platform at least 3 ft. wide, so placed that the attendants can work to best advantage either when cleaning or raising the racks.

The racks should be designed on the assumption that they act as a solid dam, and that all water behind may be drawn off. In such a case the racks and their supports would have to take care of the entire water pressure.

For the purpose of keeping floating *débris* from choking the gratings at the circulating water intakes at an American power station, a pipe has been installed just above water level in front of the grid. The pipe is drilled with ½-in. holes, and is supplied with water at 120 lbs. per square inch. The jets of water issuing from these holes wash away any leaves, sticks, and snow that might clog the grating.

Design of Head Races.

The cross-section area of a head race should be such that the water will rise to about three-quarters to seven-eighths of the height.

Wooden flumes are ordinarily rectangular and designed to carry a depth of water equal to about half the width.

Canal sections are determined by the class of material forming the perimeter and the head which it is found economical to use. The efficiency of a cross-section of a canal is greater with the value of the wetted perimeter minimum, so that a semi-circular section is the most advantageous cross-section that can be used in a channel where resistance to flow is alone considered. When the canal is lined with masonry or concrete walls it is more advantageous to make the face nearly perpendicular, and to place the batter of the wall at the back. When the canal is cut in stone or shales which will not be eroded by the flow of the water, a slope of 90° to 40° may be used. In canals dug through earth the slopes may be from 1 in 1½ to 1 in 1½. With artificial banks of earth and gravels the slope must frequently be made as low as 1 in 2.

According to Bazin, the relation between the bottom and the mean velocities in channels is the following:

$$V_b = V - 10{\cdot}87\sqrt{rs},$$

where,

V_b = bottom velocity in ft. per sec.; r = hydraulic radius;

V = mean velocity in ft. per sec.; s = hydraulic gradient or slope of channel.

The following table, calculated from the foregoing formula, gives the safe bottom velocities for different materials:

TABLE OF SAFE BOTTOM VELOCITIES.

Material of Channel.	Safe Bottom Velocity (V_b) in Ft. per Sec.	Mean Velocity (V) in Ft. per Sec.
Soft brown earth	0·249	0·328
Soft loam	0·499	0·656
Sand	1·000	1·312
Gravel	1·998	2·625
Pebbles	2·999	3·938
Broken stone, flint	4·003	5·570
Conglomerate, soft slate	4·988	6·564
Stratified rock	6·006	8·204
Hard rock	10·009	13·127

Flow of Water in Pipes, Flumes, and Channels.

The principal formula of flow in pipes, flumes and channels, is based on the formula for velocity of flow known as *Chezy's* formula, which is as follows:

$$V = C\sqrt{rs},$$

where,

V = velocity in ft. per sec.;
C = a coefficient of discharge;
A = area of cross section considered, in sq. ft.;
p = wetted perimeter in ft.;

r = hydraulic radius = $\dfrac{\text{area of section}}{\text{wetted perimeter}} = \dfrac{A}{p}$;

s = hydraulic gradient or slope of channel = $\dfrac{\text{difference of level}}{\text{distance}} = \dfrac{h}{l}$.

h = fall in ft. between points considered;
l = distance in ft. between points considered.

The formula for the flow is $Q = AC\sqrt{rs}$,
where

Q = discharge in cub. ft. per sec.

The value of the coefficient C can be determined either by Kutter's formula or Bazin's formula.

Kutter's formula is as follows :

$$C = \frac{41{\cdot}65 + \frac{0{\cdot}00281}{s} + \frac{1{\cdot}811}{n}}{1 + \left(41{\cdot}65 + \frac{0{\cdot}00281}{s}\right)\frac{n}{\sqrt{r}}},$$

where,
n = the coefficient of roughness.

Robt. E. Horton gives in 'Engineering News,' of February 24, 1916, the following category of coefficients of roughness for use in Kutter's formula :

TABLE OF 'n' FOR KUTTER'S FORMULA.

(*R. E. Horton.*)

Surface.	Perfect.	Good.	Fair.	Bad.

To find the coefficient C, having the slope S, the hydraulic radius, *r*, and the degree *n* of roughness. Turn to the division of the Table corresponding to the given slope, S. In the first column find the given hydraulic radius, *r*. In the same line with this *r*, and under the given *n*, is the proper value of C.

To find the actual, or the greatest permissible, degree n of roughness of channel, having the slope S, the hydraulic radius *r*, and either C, or the actual or required velocity, *v*.

If the velocity is given, and not C, first find $C = \frac{\text{velocity}}{\sqrt{\text{slope} \times \text{hydraulic radius}}}$. Turn to the division of the Table corresponding to the given S, and in the first column find the given *r*. In the same line find the value given, or just obtained, for C; over which will be found the required *n*.

To find the actual or necessary hydraulic radius, *r*, having the slope S, the degree *n* of roughness, and the actual or required velocity, *v*. Assume an hydraulic radius; and from the division of the Table corresponding to the given S take out the value of C corresponding to the given *n* and the assumed *r*. Then say

$$v = \text{C so found} \times \sqrt{\text{assumed hydraulic radius} \times \text{slope}}.$$

If this *v* is the same as the given velocity or near enough to it, take the assumed *r* as the proper one. Otherwise, repeat the whole process, assuming a new *r*, *greater* than the former one if *v* is *less* than the given velocity, and *vice versa*.

To find the actual or necessary slope, S, having the dimensions of the wetted portion of the channel, the degree n of roughness, and the actual or required velocity.

$$\text{Find the hydraulic radius, } r = \frac{\text{area of wet cross-section}}{\text{length of wet perimeter.}}$$

Assume one of the four slopes of the Tables to be the proper one. From the corresponding division of the Table take out the value of C corresponding to the given r and n.

For slopes steeper than ·01 per unit of length, = 1 in 100 = 52·8 ft. per mile, C remains practically the same as at that slope. But the *velocity* (being = C × $\sqrt{\text{hydraulic radius} \times \textit{slope}}$) of course continues to increase as the slope becomes steeper.

Bazin's formula for the determination of C is as follows:

$$C = \frac{157{\cdot}6}{1 + \frac{y}{\sqrt{r}}},$$

where,

y = a coefficient of roughness, whose value Bazin gives as follows for different classes of channels.

Class I. y=0·109 for smoothed cement, or planed wood.
„ II. y=0·290 for planks, bricks, and cut stone.
„ III. y=0·833 for rubble masonry.
„ IV. y=1·54 for earth channels of very regular surface or reveted with stone.
„ V. y=2·35 for ordinary earth channels.
„ VI. y=3·17 for exceptionally rough earth channels (bed covered with boulders) or weed-grown sides.

Design of Pipes.

Pressure in Pipes.

The interior pressure in a pipe due to the presence of water, and tending to burst this pipe is larger transversely than longitudinally.

The pressure in pounds per sq. in. p, determined by a head of water H expressed in feet, is:

$$p = \text{pressure in lbs. per sq. in.} = \text{head in ft.} \times 0{\cdot}44,$$

and the diametral pressure P, tending to burst the pipe, is represented by the equation

$$P = p \times \frac{d}{2},$$

where,

d = diameter of pipe in ins.

The longitudinal tension P in the pipe is equal to

$$P' = p \times \frac{d}{4}.$$

This explains why steel riveted pipes have generally a single row of rivets at the circumferential joints and two rows of rivets along the longitudinal joints.

Design of Steel Pipes.

The thickness of metal t (expressed in ins.) required to carry a certain pressure can be determined by the following formula:

$$t = \frac{(p + p')d}{2fe} + c,$$

where,

t = thickness of steel shell in ins.;
d = inside diameter of pipe in ins.;
p = pressure of water in lbs. per sq. in.;
p' = allowance for water hammer in lbs. per sq. in.;
f = allowable tensile stress of steel in lbs. per sq. in.;
e = efficiency of riveted joint
c = thickness to be added to plate for corrosion.

The permissible unit tensile stress with ordinary open-hearth steel is assumed at 16,000 lbs. The efficiency of the joint may be taken at 55 per cent. for single riveted pipe, and at 70 per cent. for double riveted pipe. The thickness to be added to compensate for the weakening of the pipe due to corrosion is about $\frac{1}{16}$ in. In large pipes under small pressure, the thickness of metal computed with the above assumptions must still be increased to give the pipe the necessary stiffness.

Design of Reinforced Concrete Pipes.

Reinforced concrete pipes are designed under the assumption that the steel takes care of all longitudinal or transversal stresses in the pipe whilst the concrete acts as a waterproof shell. It is evident that, in this case, the steel can be reduced to the minimum thickness required.

The permissible stress per sq. in. of metal can also be taken at 16,000 lbs. per sq. in.

The area of the circles forming the transversal reinforcement can be determined as follows:

Let p = total internal pressure in lbs. per sq. in.;
d = diameter of pipe in ins.;
A_s = area of steel reinforcement per lineal foot, expressed in sq. ins.;
f = permissible stress in steel in lbs. per sq. in.;

then assuming that the concrete is to take no part of the tensile stresses, we have

$$A_s = \frac{p\,d \times 12}{2 \times f}.$$

The longitudinal reinforcement is taken with an area per lineal foot of circumference equal to half the area per lineal foot of pipe as determined above.

Spacing of Pipe Supports.

Steel and concrete pipes are not always built resting on the ground, and very often they have to be carried on concrete or masonry piers resting preferably on rock, or having a bearing surface in proportion to the load carried and to the resistance of the foundations.

The spacing of the piers is determined by considering the pipe as a circular beam resting freely on supports and carrying a uniformly distributed load consisting of the weight of the pipe plus the weight of the water. This load determines a longitudinal tension in the lower side of the pipe, and this stress added to the longitudinal tension of the pressure of water caused by the static head, plus the extra head due to water hammer, should not be allowed to exceed f, the safe tensile strength of the material.

The stress, f_b, due to bending is

$$f_b = \frac{3}{2} \cdot \frac{WL^2}{S},$$

where

L = distance between supports in ft.;
W = total load in lbs. per ft. of length;
S = section modulus of the pipe.

The longitudinal fibre stress, f_t, due to water pressure is

$$f_t = \frac{pd}{4t},$$

where,

p = pressure in lbs. per sq. in.;
d = nominal inside diameter of pipe in ins.;
t = thickness of pipe in ins.

This formula applies to steel pipe, but can be utilised in the calculation of a reinforced concrete pipe, by reducing the total area of steel reinforcement per foot length to a continuous pipe of uniform thickness. This method, however, would not take into account the resistance in compression of the concrete on the upper side of the pipe.

Adding together the stress due to bending f_b and the stress due to water pressure f_t we have a total stress,

$$f = \frac{3}{2} \cdot \frac{WL^2}{S} + \frac{pd}{4t};$$

from this we can get the distance between the supports

$$L = \sqrt{\frac{2}{3} \cdot \frac{S}{W} \left(f - \frac{pd}{4t} \right)}.$$

The permissible value of f, in a steel riveted pipe, can be taken from 8,000 to 11,000 lbs. per sq. in. according to the efficiency of the joint; in a reinforced concrete pipe 16,000 lbs. per sq. in. could safely be assumed.

Design of Wood Stave Pipes.

In Canada and in the United States extensive use is made of pipes composed of wooden staves held in place by steel wires wound continuously around the pipe, or by separate steel bands or rods connected by malleable iron shoes.

The steel is designed to take care of all the stresses and the wood forms only the shell. These pipes are very cheap, and have a greater carrying capacity than either steel or reinforced concrete pipes; they have been used for heads as high as 200 ft.

The following information has been compiled from the writings of Robert E. Horton and of Andrew Swickard.

The staves are made of California redwood, Douglas fir, and Canadian red pine. Practice varies somewhat as to the thickness of staves to be used under given pressure for a pipe of given diameter. The following considerations should govern the thickness of staves to be adopted in a given case.

1. The thicker the staves the greater stability of pipe against deformation by its own weight, and accordingly the staves must be thicker for large than for small diameter of pipes.

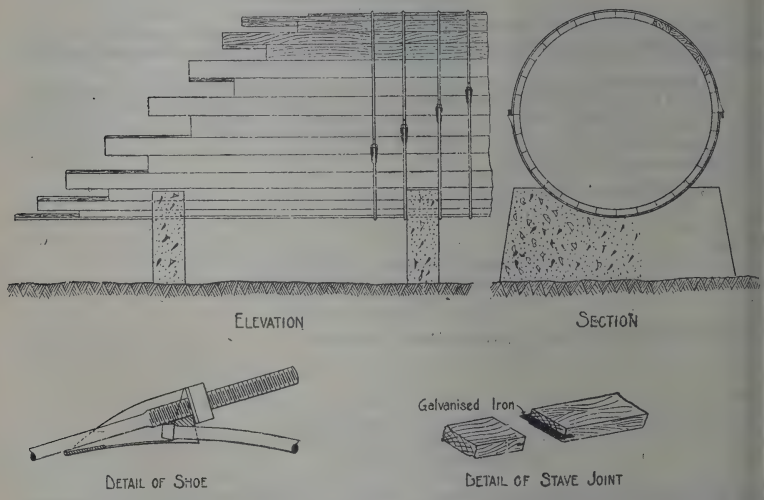

Fig. 13.—Details of Wood Stave Pipe.

2. The staves should be thick enough to prevent material loss by percolation, and accordingly should be thicker for heavy than for lighter pressures.

3. The staves should not be so thick as to prevent their being thoroughly saturated. This and considerations of economy require the use of as thin a stave as is compatible with the first two conditions named.

The following rule serves as a general guide for determining the approximate thickness of staves to be used in any case; the actual thickness of staves may be made equal to the nearest $\frac{1}{8}$ in. or $\frac{1}{4}$ in. greater thickness than shown by the rule:

$$t = 1 \text{ in.} + \frac{\text{Head in ft.} + \text{Diameter of pipe in ins.}}{100}.$$

The minimum radius of bends which may be made with continuous pipe increases with the diameter of the pipe and with the thickness of the staves. An approximate rule is

$$\text{Minimum radius, in ft.} = 4 \text{ to } 5 \times (d+4t^2)$$

where,

d = inside diameter of pipe, in ins.;

t = thickness of staves, in ins.

Wood stave pipes should be supported through an arc extending about 55° each side of the vertical axis, in order to prevent deformation of the pipe by its weight and that of the water it contains.

Stave pipes (fig. 13) are generally carried on wooden or on concrete cradles, concrete being preferable for large pipes. Joseph P. Frizell says that wooden cradles are best made of 6 in. × 8 in. or 8 in. × 8 in. timbers, spiked or drift-bolted together, of a length somewhat greater than the diameter of the pipe, and at distance apart about equal to their length. Robert E. Horton is of the opinion that the spacing of the supports is about the same for wood stave and steel pipes.

The abutting end joints of the staves are connected together by iron plates inserted in a slot sawn in for that purpose. This iron tongue should be about $\frac{3}{32}$ in. wider than twice the depth of the slot and about $\frac{1}{8}$ in. longer than the slot, allowing a projection of $\frac{1}{16}$ in. into the adjoining staves.

Creosoted wood-stave pipes put in place twenty-eight years ago were said, at the recent convention of the American Wood Preservers' Association, to be still in perfect condition. The best method of treatment for the staves was described as being the empty-cell process with 50 lbs. initial air pressure, following the creosote pressure period with several minutes' reheating at about 25° F. in excess of any previous temperature, then a vacuum of not less than 20 ins. maintained for from 30 mins. to 1 hour. By this process a satisfactory creosote penetration is obtained, and the staves come out thoroughly clean, and so dry as scarcely to soil the hand.

Area of Bands and their Spacing.

The two principal considerations governing the size and spacing of bands are as follows:—

(1) The area of section of the band per ft. length of pipe must be such as to safely withstand the water pressure plus the stress in the band due to swelling of wood when saturated.

(2) The size and spacing of bands must be such as not to produce crushing of the wood.

Taking into account both the stress due to water pressure and that due to swelling of the staves, the following formula has been derived for determining the necessary area of cross-section of metal in the bands per in. length of pipe.

$$a = \frac{pd + 200t}{2f},$$

where,

a = required area of band section per in. length of pipe;

p = pressure in lbs. per sq. in.;

d = inside diameter of pipe in ins.;

t = thickness of stave in ins.;

f = permissible unit stress in lbs. per sq. in., taken generally as 16,000 lbs.

In order to avoid dangerous crushing of the wood, the bearing pressure between bands and staves should not exceed about 800 lbs. per sq. in. of contact between the band and stave. For round bands the width of contact between the band and stave should be about equal to the radius of the band.

From these data the following formula is obtained for determining the maximum permissible spacing S in ins. between bands of given size under a given pressure.

$$S = \frac{400 \times \text{diameter of round bands in ins.}}{\text{Pressure in lbs. per sq. in.}}.$$

Shoes or Band Couplings.

The band couplings should be made of malleable iron. The weight of these shoes will vary with the size of the band and the diameter of the pipe, but the following table gives average weights for various sizes of bands, which are accurate enough for estimating purposes:

Diameter of Band, ins.	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1
Weight of Shoe, lbs.	0·35	0·40	0·65	1·00	1·75	2·75	4·00	6·00

Length of Bands.

Before the length of a band can be determined it is necessary to know how much lap-over of the rod there is in the shoe. This differs in shoes for different sizes of pipe, increasing with the increase in size of rod. However, this quantity will average about as follows for various sizes of bands :

Diameter of Band, ins.	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	1
Lap-over of Band in Shoe, ins.	$\frac{3}{8}$	$\frac{5}{8}$	$\frac{3}{4}$	$\frac{7}{8}$	$1\frac{3}{16}$	$1\frac{1}{4}$	$1\frac{1}{4}$	$1\frac{5}{8}$

The end of the rods should be upset and threaded over a length of not less than $4\frac{1}{2}$ ins. for $\frac{3}{8}$ in., 5 ins. for $\frac{7}{16}$ in., and 6 ins. for other sizes. There are three types of head in use—button, square, and tee heads. The tee head has the advantage of keeping both ends of the rod closer to the staves, and shortens the space over which the rod is raised from the staves ; it also permits the use of a shorter shoe. The length of rods under the head should be such that, after the pipe is finally tightened, at least $1\frac{1}{2}$ ins. of thread will remain ahead of the nut. The length of the rod, excluding the head, is determined in the following manner, where the rod is in one part and 6 ins. of thread is being used :

$$\text{Total length} = (d+2t+r)\pi+k+4\tfrac{1}{2} \text{ ins.}$$

where,

d = nominal inside diameter of pipe in ins. ;
t = thickness of staves in ins. ;
r = diameter of rod in ins. ;
k = lap of rod in shoe in ins.

If the rod is in two parts, the following formula applies :

$$\text{Total length} = (d+2t+r)\pi+2k+9 \text{ ins.}$$

From 68 tests on wood-stave pipe lines with diameters from 4 to 162 ins., and velocities ranging from 1 ft. to 8 ft. per sec., it was found that with diameters from 4 to 24 ins. the average value of n in Kutter's formula (p. 1319) was 0·0109, and w th diameters from 31 to 162 ins. the average value of n was 0·0124.

(*Mallett ; Flow of Water in Pipes, Vol. CCVIII, April* 1921), *Proceedings Inst. C.E.*)

Discharge of Water through Orifices.

The theoretical velocity, v, with which water flows from an orifice in the side of a vessel at a depth h from surface is the same as that of a body falling freely by gravity from height, h, viz.

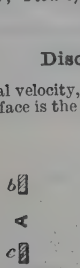

FIG. 14.

FIG. 15.

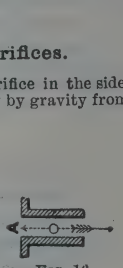

FIG. 16.

$v = \sqrt{2gh}$, but practically the converging currents produce a contraction of the jet, which assumes the form of the vena contracta, d, e, f, g, fig. 15.

h = height from surface of water to centre of orifice, in feet. v = velocity of issuing water

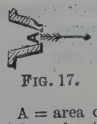

FIG. 17.

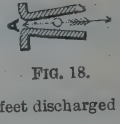

FIG. 18.

in feet per second. A = area of orifice, in feet. Q = cubic feet discharged per second. g = coefficient of terrestrial acceleration.

$$v = m\sqrt{2gh}. \qquad Q = mA\sqrt{2gh}. \qquad 2g = 64{\cdot}4 \qquad \sqrt{2g} = 8 \text{ practically}$$

m.	
·625.	Where the orifice is a thin plate, bc (fig. 14), with thickness less than $\frac{1}{2}$ smallest dimension of orifice.
·97.	Orifice shape of vena contracta, d, e, f, g (fig. 15) ; A is measured at f, g.
·82	Orifice with an adjutage (fig. 16) ; O = $2\frac{1}{2}$ to 3 times least dimension at A.

m.	
·95.	Sides converging at angle of 13½° (fig. 17). m depends on diameter and angle of convergence.
1·46.	Sides diverging at angle of 5° 6′ (fig. 18). C = 9 times least dimension at A, which is of form of vena contracta. (Seldom used.)
·548.	Where 2 sluices in thin plates are so close as to interfere with each other; m being reduced from ·625.
·62.	For sluices of moderate size in lock gates, etc.
·82.	For narrow-bridge openings.
·92.	For very large sluices and bridge openings.

The conclusions drawn from investigations made by Messrs. *Dempster Smith* and *J. W. Walker* * are:—

(1) That above a certain critical head (about 2 ft. of water) and a critical orifice diameter (2½ ins.), the experimental values of the coefficient of contraction for different types of orifice agree closely with the values deduced from hydrodynamical theory.

(2) That the coefficient of contraction varies with the head and orifice diameter in a manner closely represented by the formula

$$C = 1 - \frac{a}{e^x} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where a is a constant and x a function of the head and orifice diameter.

(3) That in the case of the coefficient of contraction for sharp-edged orifices

$$a = 0{\cdot}39;$$
$$x = \frac{0{\cdot}15}{a^3\, h^{0{\cdot}125}},$$

where h is the head causing the flow.

(4) That formula (1) may be extended to include the effect of a variation in the pipe or reservoir area. The formula for C then becomes

$$C = \frac{1}{1 + \left\{\frac{a}{e^x - a}\right\}(1 - a^2} \quad . \quad . \quad . \quad . \quad (2)$$

where x and a have the same significance as before and a = ratio $\frac{\text{orifice area}}{\text{pipe area}}$.

To raise a River a certain Height by a Weir.

Q = discharge of river in cubic feet per second; h_1 = height by which river is to be raised in feet; h_2 = depth of top of weir below original surface of water necessary to raise surface by height h_1; h_a = head corresponding to velocity of approach; l = length of weir in feet; m = coefficient of contraction = ·628; $2g = 64{\cdot}4$.

$$h_2 = \frac{Q}{ml\sqrt{2g(h_1 + h_a)}} - \tfrac{2}{3}\frac{(h_1 + h_a)^{\frac{3}{2}} - h_a^{\frac{3}{2}}}{\sqrt{h_1 + h_a}}.$$

If h_a is not taken into account, then

$$h_2 = \frac{Q}{ml\sqrt{2gh_1}} - \tfrac{2}{3}h_1.$$

SECTION XXV

PART IV

WATER-PRESSURE ENGINES—PELTON WHEELS—TURBINES

Water-pressure Engines.

SINGLE-ACTING ENGINES

consist of single cylinder and piston. The water is admitted under the piston, raises it, is allowed to escape, and the piston falls by its own weight. Average velocity of piston should not exceed 140 feet per minute. Stroke should be as long as possible, generally from 6 to 10 feet.

Water-pressure engines are also made rotatory with single or double acting cylinders, and single and double acting rams are extensively used for working cranes, dock gates, etc., the stroke of the ram being multiplied by gearing or chain tackle. The pressure generally used is 700 lbs. per square inch.

POWER OF WATER-PRESSURE ENGINES.

$P = 62{\cdot}42Qh \times {\cdot}66$ to ${\cdot}8$ ft. lbs. per sec.; $\quad$ H.P. $= Qh \times {\cdot}07491$ to ${\cdot}09080$,

where,

Q = cub. ft. of water per sec., h = height of fall, in ft.

Diameter of supply-pipe = diameter of cylinder $\times$ ·41 for single cylinder engines, = diameter of cylinder $\times$ ·68 for double cylinder engines.

EXAMPLE.—A single-acting pressure engine has a pressure cylinder 50 ins. in diameter, a head of water of 132 ft., a stroke of 10 ft., and is worked 4 to 7 strokes per min.

$$Q = \frac{25^2 \times 3{\cdot}14}{144} \times 10 \times \frac{4}{60} = 9{\cdot}1 \text{ cub. ft. per sec.}$$

H.P. $= 9{\cdot}1 \times 127 \times {\cdot}09080 = 105$ horse-power, with 4 strokes per min., or 184 with 7 strokes The actual work was about 168 horse-power.

PELTON WHEELS

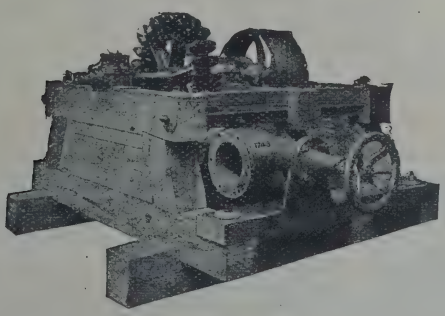

FIG. 1.

In these wheels, fig. 1, the water striking the buckets in the middle is deflected to both sides equally, and in such a way that the discharge from one bucket clears the one following. The

construction of the buckets is shown in fig. 2. An improvement of the Pelton semi-cylindrical bucket is the Doble bucket, fig. 3, each half of which is ellipsoidal in form, and has a part of the outer lip cut away, so as to avoid hitting the jet when moving under it.

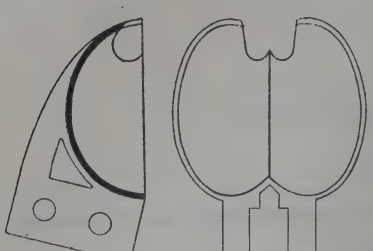

FIG. 2.—Pelton Bucket.

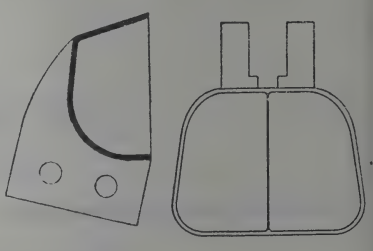

FIG. 3.—Doble Bucket.

THE ENGLISH ELECTRIC BUCKET ATTACHMENT FOR IMPULSE WATER TURBINES.

(The English Electric Co., Ltd.)

Fig. 4 shows the method of attachment in detail. For each bucket it consists of one tapered forged-steel bolt passing through a bush of chrome nickel steel, the external surface of which is cylindrical, whilst the interior is reamered to a taper. The bush is split longitudinally along its whole length. The holes through the disc and the lugs of the bucket are, therefore, cylindrical, so that spare buckets can be completely finished in the shops, and are interchangeable without difficulty; no reamering is necessary on site, and prolonged stoppage of the plant is obviated.

The tapered bolt is provided with nuts which, on being tightened, cause the bush to expand and tighten against the wall of the cylindrical hole; the force due to this taper is considerably greater than that exerted by the jet. At the same time, the lugs of the bucket are tightened by the nuts with absolute security against the two faces of the disc. These nuts are secured by locking washers, which are bent over both the boss of the lug and the face of the nut.

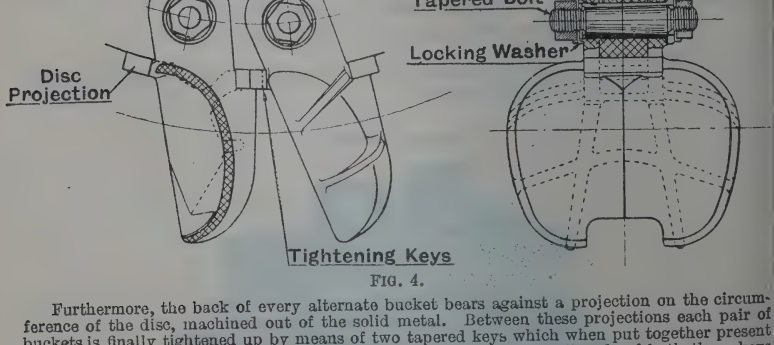

FIG. 4.

Furthermore, the back of every alternate bucket bears against a projection on the circumference of the disc, machined out of the solid metal. Between these projections each pair of buckets is finally tightened up by means of two tapered keys which when put together present parallel faces to the bucket surfaces. After final assembly the small ends of both these keys are bent to prevent any movement. By this means, the buckets are tightened under great pressure against the disc projections and the circle of buckets resists the blows of the jet as rigidly as a solid mass.

Not only is the attachment remarkably strong, but the one-bolt fastening works under better conditions than the two-bolt attachment generally used. It is extremely difficult to drill a series of pairs of holes in the cast-steel disc and buckets with the necessary accuracy to render the buckets interchangeable, and to ensure that the stresses are shared equally by each bolt. There is always the danger of one bolt bearing nothing whilst the other takes the whole of the

strain. With one bolt and one key this danger is overcome; the bolt bears the shearing, and the key the compressive stresses, thus the forces are transmitted to the disc in the best possible manner.

Proportion of Parts of Pelton Wheels.

(1.)

The area of the jet should not exceed 0·1 the projected area of the bucket, or the diameter of the jet should not exceed 0·3 the width of the bucket. The ratio of the wheel diameter to jet diameter should not be lower than 9, 12 being a common value, so that the diameter of the wheel in feet should about equal the diameter of the jet in inches.

The size of the jet depends on the amount of power desired, per unit, under the given head; the peripheral speed of the wheel varies between 0·43 and 0·47 of the theoretical jet velocity. Two and three jets are sometimes used upon one wheel, but a single jet is preferable. Sometimes two wheels are used to drive a single generator mounted between them.

The efficiency of the Pelton wheel has been found to exceed 86 per cent. Since this wheel operates by utilising the kinetic energy of the water, it is best adapted to a small discharge under a high head: its range of usefulness varies from 50 foot heads to 3,000 and even 5,000 foot heads.

A recent Gunther Pelton wheel, installed in India for electric power and lighting, develops 100 b.h.p. under 600 ft. head, and the oil-pressure governor works on to the jet deflector, the spear rod regulator being hand-controlled.

The majority of impulse wheels are now equipped with steel buckets, as the average of steel castings has been greatly improved, so that the present steel bucket will outwear the bronze bucket.

(2.)

(Contributed by W. Gunther & Sons, Oldham.)

The diameter of a Pelton wheel is fixed by the speed required. Theoretically and practically the most efficient wheel velocity is one-half the jet velocity.

$$\text{Velocity of jet in ft.-sec.} = 0{\cdot}95 \text{ to } 0{\cdot}97 \sqrt{2gH}.$$

where,

$$\text{Velocity of wheel in ft.-sec.} = V = 0{\cdot}47 \sqrt{2gH},$$

H = head in feet.

When the speed required is known or can be fixed, the diameter, D, of the wheel is given by—

where,

$$D = \frac{V\ 60}{n\ \pi}$$

V = velocity of wheel in ft.-sec.; n = revolutions per min.

This is the diameter of an imaginary circle having as a tangent the line of action of the centre of the jet.

The diameter of jet required may be found as follows:—

$$\text{Diam. of jet in inches} = \sqrt{\frac{Q \times 0{\cdot}401}{\sqrt{H}}};$$

where,

Q = quantity of water in cu. ft. per *minute*; H = head in *feet*.

The ratio of the diameter of the jet to the diameter of the wheel should not normally be below 1 : 12.

The proportions of the wheel buckets are given in terms of the jet diameter, and may generally be taken as follows:—

width of bucket, 3·2 to 3·5 × jet diam.; height of bucket, 2·7 × jet diam.; depth of bucket, 1·2 × jet diam.

When two jets are used on one wheel the size of the buckets will be materially less than if one jet were used, and this often means a considerable saving. Various combinations of jets and wheels are sometimes used, e.g. two wheels keyed to one shaft, each with either one or more jets, and so on, but not more than four jets, at intervals of 90 degs., should play on one wheel, or interference takes place. In actual practice it is rarely found advisable to use more than two jets per wheel.

Pelton Wheel Regulators.

General.

The section of the nozzle is either square or circular, but more generally circular, with a needle, fig. 5, to secure a more uniform velocity in all parts of the jet; this needle can be moved back or forward by the governor, varying the area of the opening and regulating the amount of water discharged. For very high heads, where the interruption or partial suppression of flow by such an arrangement might involve danger to the pipe-line, deflecting nozzles of various kinds are employed. The movement of a regulating nozzle of this description is accomplished with comparatively little expenditure of energy, and thus the control of Pelton wheels is simple unless affected

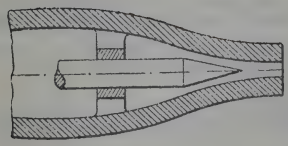

Fig. 5.

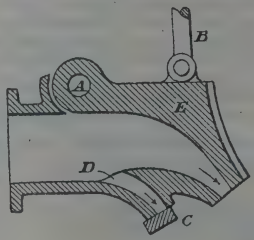

Fig. 6.

by irregularities. A deflecting nozzle, as used by Messrs. Theodor Bell & Co., is shown in fig. 6. This nozzle is rectangular in section, the upper side being formed by the piece E pivoted at A. This is moved by the governor attachment B, so as to increase or diminish the area of the nozzle at the mouth. A secondary nozzle D is closed by a cap C, which also rotates about the pivot A, and is moved through the same angle as E. As the two nozzles have the same width, a partial closure of the larger nozzle is compensated by an opening of the smaller, so that the spouting area is always a constant, and the flow through the pipe is steady, while the wheel receives that fraction of it which is required to maintain the speed constant at all loads.

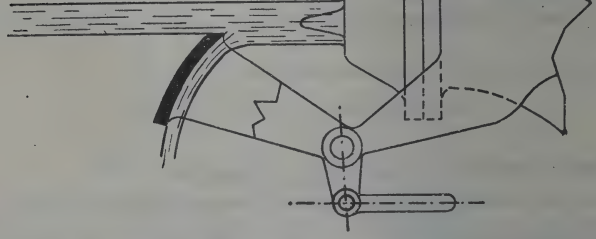

Fig. 7.—Needle Nozzle with Deflector.

The foregoing device, however, is wasteful of water even with the best of attention. Since the water hammer caused in the pipe by a sudden opening of the nozzle is less dangerous than the hammer due to the sudden interruption of the flow, a device, fig. 7, has been perfected, consisting of an automatic jet deflector and an ordinary nozzle needle, which causes the governor to act on the deflector only in case of closing, the needle being afterwards slowly closed by means of a dash-pot mechanism, whilst the deflector becomes tangential to the reduced jet. When the governor moves to increase the discharge of the nozzle, it controls simultaneously and rapidly the deflector and the needle.

Combined Spear and Deflector Regulator Controlled by Shaft Governor.

(Gilbert Gilkes & Co. Ltd., Sole Makers and Patentees.)

For high-falls (100 ft. and upwards), Pelton wheels or other impulse turbines may be controlled by an arrangement similar to that shown in fig. 8, as made by *Gilbert Gilkes & Co. Ltd.*, of Kendal.

The arrangement consists of a pendulum mounted upon the turbine shaft and coupled direct to the deflector shaft, the design of the deflector being such as to impose the least resistance to the passage of the water through the jet.

Movement to the spear is given by a piston moving in a hydraulic or oil-pressure cylinder fixed to the end of the branch pipe.

The position of the spear is dictated by a poppet valve controlled by levers and links connected to the deflector shaft, and so arranged that if the load be thrown off the deflector

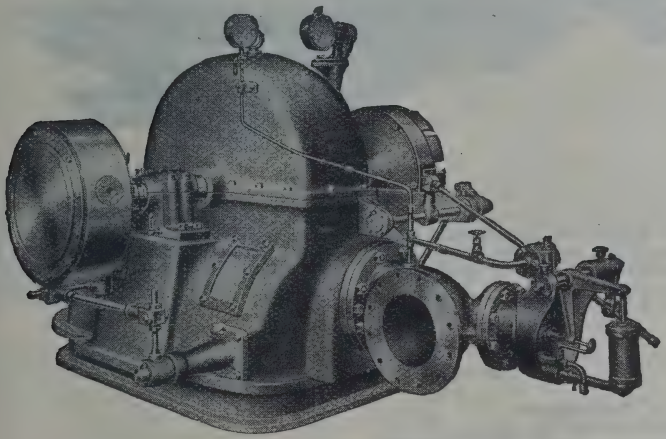

Fig. 8.

is brought instantaneously into the jet, the spear slowly following and the deflector finally taking up a position just clear of the jet. If the load is thrown on, the spear is drawn rapidly back.

When economy of water on reduced loads is immaterial, as in the case where the supply is from a stream without storage, the automatic spear-following combination is dispensed with, a hand-regulated spear being substituted.

The pendulum being mounted directly on to the shaft ensures a perfectly steady drive, saves space, and is immune from all risks due to breaking of chains, belts, etc.

As the pendulum is connected directly to the deflector without the intermission of servo-motors, etc., extreme rapidity of action is obtained, the movements being instantaneous and dead time eliminated, the results showing a momentary variation of less than 1 per cent. with full load thrown off.

The 'Seewer' Impulse Wheel Regulator

(The English Electric Co., Ltd.)

The design of this governing device for impulse turbines is based on the principle of the rapid destruction of the energy of the jet. This is obtained by placing blades in the nozzle at a slight angle to the normal direction of the water stream, so that the jet issuing from the nozzle no longer remains cylindrical, but is dispersed in a hollow conical form, thus diverting the energy of the jet from the buckets.

The blades, normally withdrawn into the hollow spearhead, fig. 9, are carried by a movable ring which is connected to the speed governor by a rod passing through the spindle of the spear. When a sudden drop in load occurs and the speed rises, the blades are pushed forward into the water stream, giving it a whirling movement which makes it lose its useful energy. Fig. 9 shows the blades advanced into the position for dispersing the jet.

Fig. 10 is a diagrammatic arrangement of this governing device for a single-jet impulse turbine.

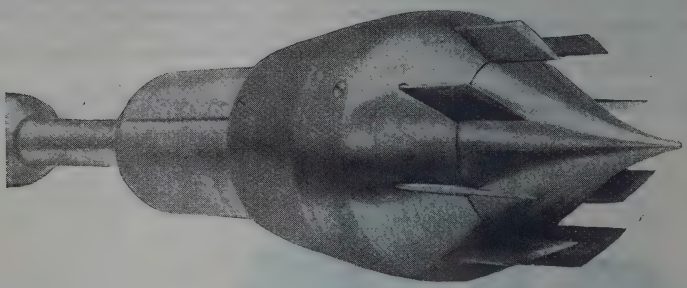

FIG. 9.

On a sudden drop in load with its attendant rise in speed, the governor pendulum rises; point 1 being a momentary fulcrum, point 2 must fall, depressing the plunger in the distributing valve and thus allowing the oil to flow from the pump to the right-hand piston chamber of the guide-blade servomotor, and at the same time opening the exhaust from the left-hand chamber. The resultant oil pressure in the right-hand chamber, in conjunction with a spring, pushes the piston to the left and the guide blades are moved forward into the water stream by the action

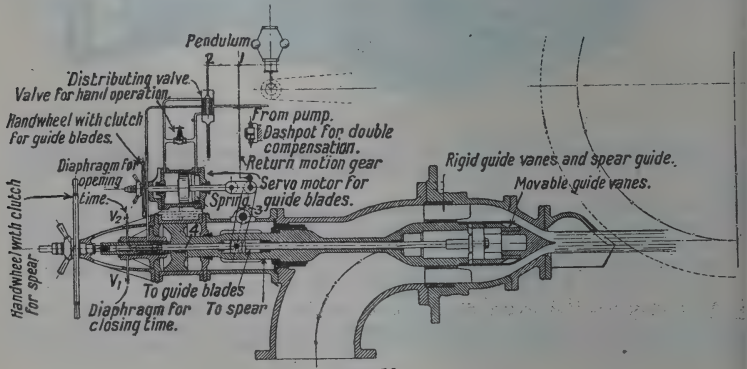

FIG. 10.

of the lever 3 on the spindle attached to the movable ring. At the same instant the rear end of the spindle 4 acts as a distributing rod and allows oil under pressure to pass into the left-hand chamber of the spear servomotor and connects the right-hand chamber to the exhaust; the spear is thereupon closed. The closing movement is controlled by the diaphragm V_1, which prevents the oil from flowing too quickly to the exhaust and thus obviates any undue pressure rise in the pipe-line.

For an increase in load the reverse operation takes place, and in this case the diaphragm V_2 controls the speed with which the spear is withdrawn and the normal operation of the jet is resumed.

In the arrangement, the strokes of the primary and secondary mechanisms—*i.e.* the blades and the spear—being always identical, no sort of cam device is required, which avoids troubles in the adjustment of governing apparatus. The spear shaft, together with the rear part of the guide blade rod, forms the distributing apparatus of the spear servomotor, thus simplifying the whole apparatus; and, being rigidly controlled by the servomotors, any danger of its getting out of order is obviated.

As the blades have no important force to sustain, they are light in design, and this fact, in conjunction with their small stroke, enables them to destroy the energy of the jet very quickly—in fact, almost instantaneously. This advantage is of the utmost importance as regards the speed variation .and stabilises the running of the set considerably.

Another advantage of the governing device is the small amount of energy required, as the only effort to be overcome is that due to friction; this friction is due chiefly to the reaction of the whirling water, but is only a small percentage of the force exerted by it. Owing to this fact, the governing device requires a governor of small dimensions only, taking up less space than usual in the power house.

In case of breakdown of the governor, the governing mechanism acts as a security device, the dispersing blades being automatically pushed forward by the spring of the servomotor, thus spreading the jet and avoiding accidents.

The sensitiveness of the governing device is such that good regulation is obtained without adding to the moment of inertia found in a generator of normal design; this is a consequence of considerable significance, as it is frequently found that with ordinary methods of jet control either an abnormal design of generator is called for or else a separate flywheel has to be provided.

As the results of tests taken on a 3,300 b.h.p. turbine at the Kinlochleven Power Station, running under 900 ft. pressure, it was noticed that when the full load was suddenly thrown off, the maximum speed variation was only 3·45 per cent. for a permanent speed variation adjusted at 0. When operating at fractions of full load, the speed variations on removing the load were still smaller, these qualities conducing to remarkably steady running. The pressure rise was also very low, amounting in the tests to a maximum of only 2½ per cent. for the combined movement of both the dispersing blades and the spear. For the blades alone the corresponding rise in pressure would, of course .be still less, and in fact for all practicable purposes negligible.

Notes on Regulators.

The best makes of hydraulic regulators for medium and high falls will govern within the following limits, the per cent. being that of the mean speed:

For a sudden variation of load of 25 per cent.	4 per cent.
„ „ „ 50 „	6 „
From no load to full load	10 „

The relative speed with which gates may be closed by hydraulic and mechanical regulators is greater for the hydraulic, the ratio being generally about 5 to 1 in favour of the hydraulic.

TURBINES.*

Classification of Turbines.

Action, Impulse, Tangential, or Pressureless Turbines.

In these turbines the passages are never completely filled with water and the flow of water is always under atmospheric pressure. During flow through the wheel the absolute velocity of the water is reduced as the water gives up its kinetic energy.

Reaction, or Pressure Turbines.

In these turbines the wheel passages are completely filled with water under a pressure which varies throughout the flow. During this flow through the runner, both the pressure and the absolute velocity of the water are reduced as the water gives up the energy to the wheel.

---

* The following books have been consulted and quoted: *Hydraulic Turbines*, by R. L. Daugherty; *Elements of Hydraulics*, by S. E. Slocum; *Water-Power Engineering*, by Daniel W. Mead; *Water-Power Plants and the Type Characteristic of Turbines*, by W. Basshuus; and *La technique de la houille blanche*, by Etienne Pacoret.

Direction of the Flow of Water.

In the radial outward flow, or centrifugal turbines (Fourneyron type, fig. 11), the guide-vanes ring is contiguous to the runner, and the water passes through the runner whilst moving away from the axis of rotation but in the plane perpendicular to it.

In the parallel, or axial flow turbines (Jonval type, fig. 12), the guide-vanes ring is superposed to the runner, and the water passes through the runner buckets whilst moving along a circular cylindrical surface having for axis the shaft of the turbine.

In the radial inward flow, or centripetal turbines (Francis type, fig. 13), the guide-vanes ring is contiguous to the runner, and the water moves towards the axis of rotation in a plane perpendicular to it.

In the mixed (radial, inward, and axial) flow turbines (American type, fig. 14) the water enters the wheel radially, in the direction of the axis, and, during its flow through the runner buckets, turns and discharges axially.

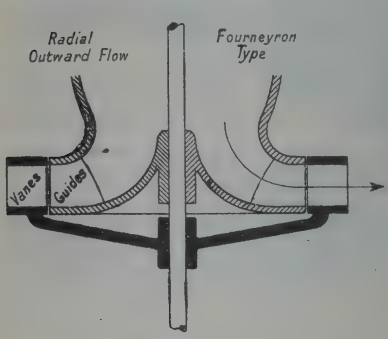

Fig. 11.

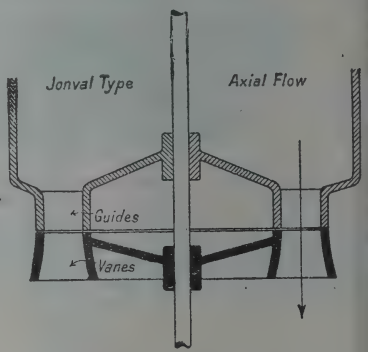

Fig. 12.

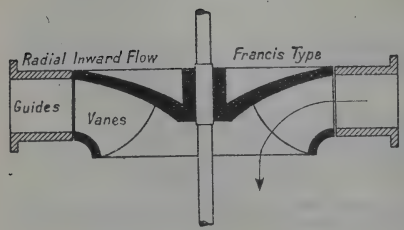

Fig. 13.

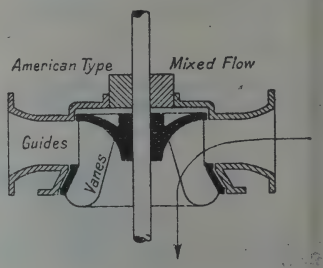

Fig. 14.

Position of the Shaft.

Turbines have either (*a*) an horizontal shaft, or (*b*) a vertical shaft; the latter are further classified as right-hand or left-hand turbines according to the direction of their rotation. If in looking down upon the wheel from above the rotation appears clockwise it is called a right-hand turbine. The reverse of this is a left-hand turbine.

Turbine builders have now reduced their production to three types, viz. the tangential or Pelton wheel, the centripetal flow or Francis turbine, and the helico-centripetal or American turbine, each of which satisfies special conditions.

Types of Turbines.

The Francis and the American turbines (both of which are of the reaction type) have superseded all the others, because they are cheaper to build, smaller, more easily regulated, and have a higher speed than the turbines of the Fourneyron or Jonval type.

The Francis Turbine.

Some of the main reasons for the pre-eminence of the Francis turbine over all other types of low and medium head turbines lie in its adaptability, since it can be designed either to pass large or small volumes of water for a given diameter of wheel, and can be constructed for low or fairly high heads, and in the relative ease with which it may be governed owing to the short stroke of its regulating apparatus, thus rendering it particularly suited for electrical work. Francis turbines may be used with either horizontal or vertical shafts, and with one, two, three, four, or even more wheels upon one shaft. The regulating device consists of a number of pivoted guide blades spaced round the circumference of the runner, and simultaneously moved to open or to close by means of a floating ring to which they are attached and which is connected to the governor by a lever and rocking shaft.

As a basis of comparison between Francis turbines, the specific speed of the runner is used. This term 'specific speed,' which was evolved by Prof. Camerer, is the speed of a runner which, operating under a fall of 1 ft. (or 1 metre), produces 1 h.p. The formula for specific speed, n_s, is given by—

$$n_s = \frac{n}{H} \sqrt{\frac{N}{\sqrt{H}}}, \text{ or, } n_s = \frac{n\sqrt{N}}{H^{\frac{5}{4}}}$$

where,

n = revs. per minute; H = head in ft. (or metres); N = horse-power.

H may be in ft. or metres, and the result gives respectively the specific speed in English or metric denominations.

The speed classification, according to Camerer, is as follows:

n_s (metric) 50–120 : slow speed runner; 120–250 : normal speed runner; 250–400 : high speed runner.

n_s = over 400 is known as an 'express' runner.

Recent progress has resulted in the construction of runners having still higher specific speeds, but these are mainly of interest in the case of very large powers under low heads, and also are only in the early stages of development. Slow-speed runners are always narrow wheels, and are largely used in spiral Francis turbines; high-speed runners have wide entrance and discharge areas.

Runners of Francis turbines are mostly made in series, geometrically identical for the same specific speed, all the dimensions varying in proportion to the diameter of the wheel.

All possible arrangements of Francis turbines may be considered under two heads—viz. 'Open-flume' and 'Cased' turbines.

Open-flume Francis Turbines.

On relatively low falls, up to about 30 ft., in dealing with large quantities of water, the Francis turbine is frequently made without casing and placed in an open flume or pit, the turbine shaft being carried through the end or retaining wall of the head water chamber. The runner is usually of a high specific speed type. This arrangement proves to be a very convenient one for direct coupling to an electric generator. Either a single runner, or two or more, may be carried on the same shaft. Fig. 15 shows a section through a twin turbine of this type, as made by Messrs. W Gunther & Sons, Oldham, for direct coupling to an electric generator. On smaller plants the bearing farthest from the driving side is usually submerged, but in the plant shown this bearing is placed in a water-tight casing accessible from above the head water level, so that the bearing may at all times be examined.

Cased Francis Turbines.

Circumstances do not always permit of low-fall Francis turbines being placed in an open flume—*e.g.* when they are to be installed in existing buildings, or when the lay of the ground is more suited to a pipe conduit. Such turbines are then enclosed in steel or cast-iron casings, cylindrical or spiral. In fig. 15 a 500 h.p. twin turbine of Messrs. Gunther is shown, in which

GUNTHER & SONS' TURBINES.

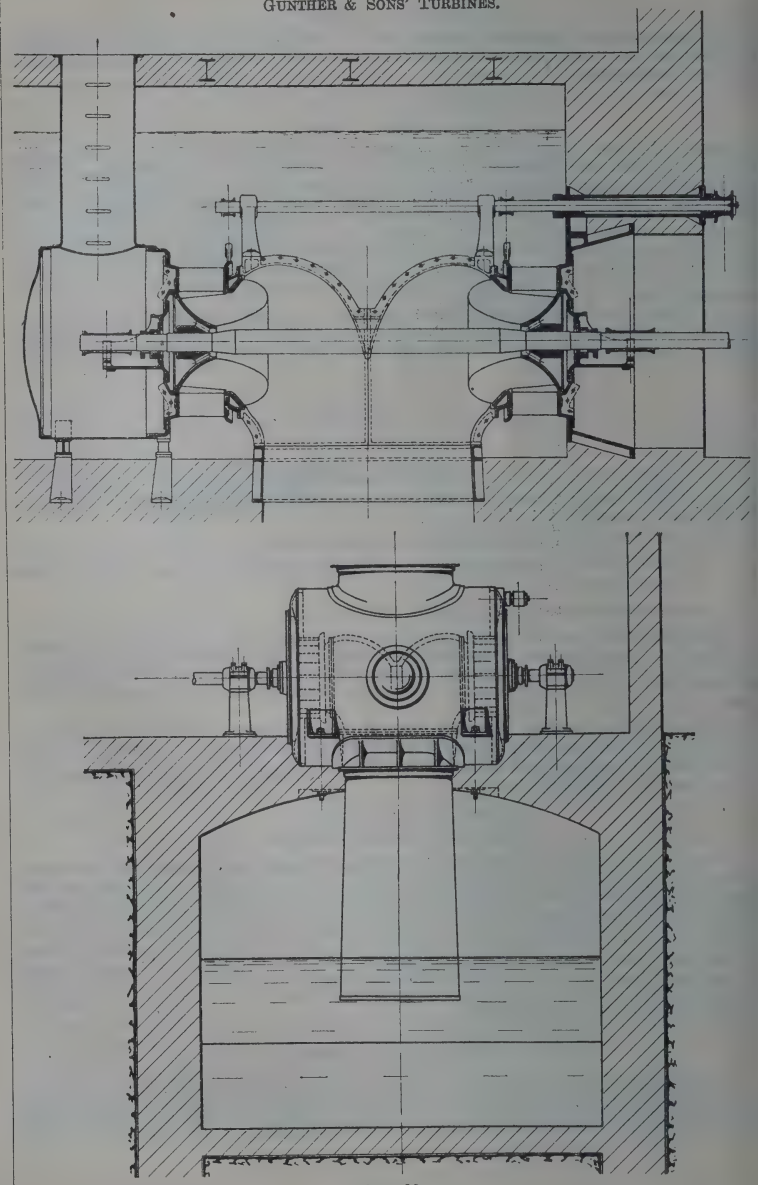

FIG. 15.

the water discharged from the two runners passes into a suction chamber formed by a double bend, and is discharged centrally into the suction tube, the whole being enclosed in a steel casing. The ring regulation of the guide ports for this arrangement of turbine may be inside or outside the casing, the more modern but more costly way being to have the regulating gear outside, and thus out of contact with the water.

One of the most valuable modern developments of the Francis turbine has been in the solution of the problem of dealing with medium heads, i.e. between about 50 ft. to 200 ft. For this range the high-speed runner would have an inconveniently high number of revolutions per minute, and a Pelton wheel may be unsuitable for several reasons—the speed may be too slow, or in order to deal with the quantity of water the Pelton wheel may become very large and heavy, or requiring perhaps two wheels on one shaft, with two or more nozzles to each. For such cases a slow specific speed Francis runner with a spiral casing of cast iron or steel may be used to advantage. In a spiral casing much higher velocities of the water may be taken, thus reducing the size and cost of the installation. The regulating arrangements are placed outside the spiral casing, and are easily accessible. A spiral Francis turbine (fig. 15, p. 1380), made by Messrs. W. Gunther & Sons, of Oldham, for driving a textile mill by means of a rope drive, has a head of 62 ft., with an output of 500 b.h.p. Regulation is effected by an oil-pressure governor.

The range of usefulness of the spiral Francis turbine naturally overlaps that of the Pelton wheel in many cases, spiral turbines having been used up to 800 ft. head or more, and the choice of a Pelton or a spiral Francis turbine is not always a rigid one.

American Turbines.

The American turbine, or mixed flow turbine, fig. 14 (p. 1378), is a modification of the Francis turbine, resulting from a demand for higher speed and power under low heads. Higher speed is obtained by reducing the diameter of the runner, greater power by increasing the capacity of the runner, making the buckets deeper and reducing the number of vanes. Since this decreased the discharge area, the vanes were curved so as to discharge axially; combined together these alterations have produced the high-speed high-capacity mixed-flow runner of to-day.

The best peripheral wheel speed for a reaction turbine varies between 0·57 to 0·87 of the theoretical spouting velocity of the water under the head considered. The efficiency of the modern reaction turbines is high, ranging between 80 and 85 per cent. under average conditions, and going up to 90 and 92 per cent. under the most favourable conditions.

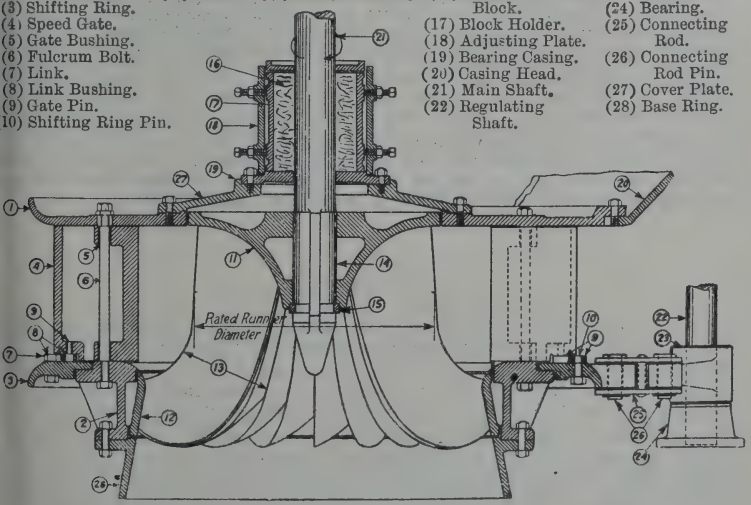

FIG. 16.—American Turbine Nomenclature.

British Turbines.

The Little Giant Double Turbine.

(*S Howes, London.*)

The form of the wheel of this turbine is shown by fig. 17, and general views of vertical forms of complete turbines by figs. 18 and 19.

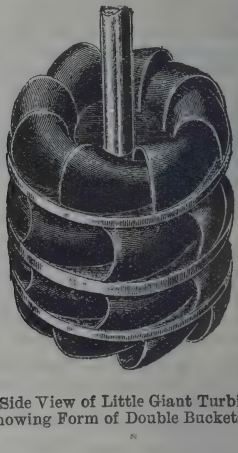

Fig. 17.—Side View of Little Giant Turbine Wheel, showing Form of Double Buckets.

The Little Giant is a double turbine having two tiers of buckets, or, strictly speaking, two turbines keyed to the same shaft, one above the other, and both running in the same case, the upper tier discharging at the top, and the lower one under the bottom of the case. The shaft is supported at the bottom end, and revolves upon an adjustable lignum-vitæ step in the bottom bridge-tree. The case is made of iron in the form of a scroll. This scroll, for larger sizes, is made of boiler-plate, which is planed parallel on the sides, and is held firmly between the cast-iron top and bottom plates by bolts. The case is supported by the bottom bridge-tree, which is bolted firmly to it. The bridge-tree is bolted firmly to the bottom of wheel-pit, upon which it rests. The gate box is made of cast iron and bolted to the case. The gate is also made of cast iron, and the surface of it, as also the ways or seat upon which it slides, are planed, thus forming a perfectly watertight joint. The pressure of water always holds the gate to its place, and the joint remains tight as the gate wears. The gates for the larger sizes of turbines, particularly if to be used under high heads, are mounted upon friction rollers.

The Division Plate.

Figs. 18 and 19 each show an iron plate passing horizontally through the turbine case, and dividing it into two compartments corresponding to the two tiers of buckets, one set being above this plate, discharging at the top of the case, the other below the plate and discharging at the bottom; in fig. 18 the plate is shown as shut down, and in fig. 19 the plate is raised. Referring to fig. 19, the gate is shown raised clear up, or at 'full gate,' admitting the water to both tiers of buckets with the full pressure due to the head, giving the full power of both parts, or of the whole turbine. If but one-half of the power of the turbine were required, the gate could be dropped or closed down to the division plate, thus shutting the water off from the upper tier, but maintaining the full pressure on the lower buckets, which would give one-half the full power with half the quantity of water, thus obtaining as high a percentage of power at half-gate as at full-gate, which could not be done if there was only one set of buckets. If no division plates were used, the full pressure of water due to the head would be on the turbine only when the gate was full open, but when used

Horizontal Little Giant Double Turbine.

(S. Howes, London.)

There may be many situations where a turbine placed upon a horizontal shaft can be used to better advantage than one on a vertical shaft. By using a horizontal turbine and placing it

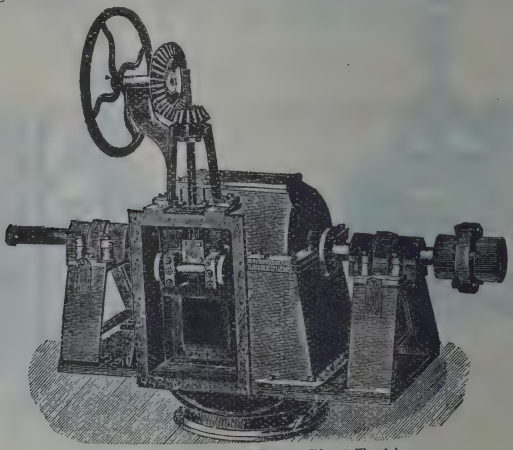

Fig. 20.—Horizontal Little Giant Turbine.

some distance above tail water, nearly the whole effect due to the head can be obtained with an air-tight discharge tube. This mode of setting a turbine (fig. 20) admits of placing a pulley directly on the turbine shaft, and belting to the line shaft.

Low Fall 'Gilkes-Francis' Turbines.

(Gilbert Gilkes & Co. Ltd., Kendal.)

The type of Francis turbine shown in fig. 21 is a medium-speed wheel (specific speed 63·0 r.p.m. in ft.-lbs. sec. units) which has been found a very useful type for small and medium powered installations. This turbine can be arranged with its shaft vertical, as shown in fig. 21, or can be fixed as a horizontal shaft turbine.

The connection of the movable guide vanes by a chain of links (as shown in the fig.) is

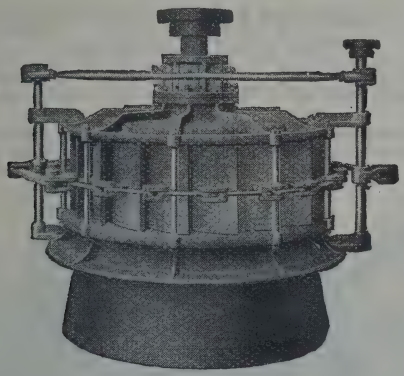

Fig. 21.

found to have a long life under ordinary working conditions, and is found to require less power than by any other method.

The vanes are so pivoted that they are as nearly as possible balanced in all positions. This fact is of great importance when it is required to control the turbine speed automatically by a governor.

Fig. 22.

All the wearing parts of the guides themselves and their connecting links are bushed with bronze and the pins are made of hard steel.

The wheel shown in fig. 22 is made of steel buckets bent to mathematically accurate curves, and then cast into an iron boss and outer skirt.

The wheel discharges to the tailwater through a cast iron flume or tail pipe, and when the turbine is arranged for a horizontal setting a cast iron discharge bend and tapered tail pipe is fitted.

For the vertical setting it is strongly recommended that the weight of the rotating parts be carried on a suitably designed ball thrust bearing arranged above the head water level. This type of bearing is much to be preferred to the lignum vitae pivot bearing under the water. The latter though very simple and cheaper than the above water suspension bearing, may give trouble, especially if the water contains much sand or grit in suspension. The pivot is in any case difficult to inspect and costly to renew.

Medium Fall 'Gilkes-Francis' Turbine.

(Gilbert Gilkes & Co. Ltd., Kendal.)

Fig. 23 shows a turbine installed at San Juan Mines, in the Argentine. It is designed to develop 750 h.p. when using 7,270 cub. ft. of water per minute under a head of 70 ft. and running at 500 r.p.m.

Owing to the comparatively high speed in relation to the head, two runners are employed, each with its own casing but discharging into a central suction flume common to the two

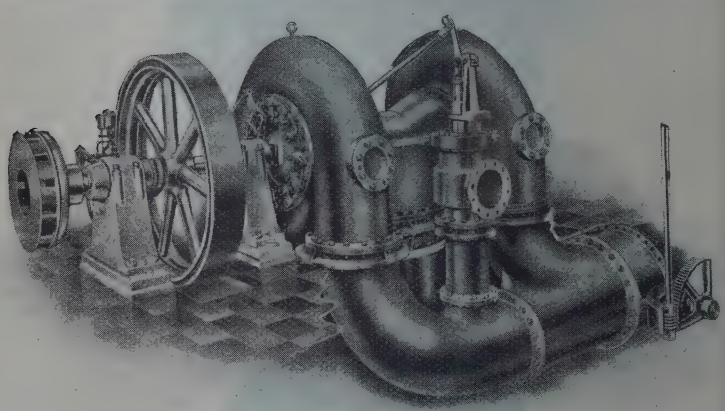

Fig. 23.

wheels, thus putting both wheels into balance and avoiding the necessity of thrust bearings. The casings are of the spiral form, which allows the kinetic energy of the water flowing through the pipes and casing to be utilised with a minimum of loss. The runners and guide blades are of the Francis type, the former being constructed with steel buckets cast into a c.i. boss and skirt.

The guide blades are of cast steel, working in phosphor-bronze bushes, and have a stem cast on which is accurately turned and carried through glands to the outside of the casing; on the end of each stem is keyed a c.i. lever, the lower being coupled together by means of bronze bushed links. Two of the stems are coupled by means of special levers to the governor. By this means all pins, joints, etc., are placed outside the turbine, where they are not affected by the action of the water and can easily be lubricated. Although this method of outside gate mechanism is rather more costly in the first place, its extra cost is soon compensated for by smoothness in running and absence of repairs. It has been known that pins acted upon by the water, assisted sometimes by electrolytic action, have required renewing after a few months' wear, entailing the shutting down of the plant for a considerable time to gain access to the inside of the turbine.

The speed of the set is controlled by a Gilkes oil pressure governor, assisted by a cast steel flywheel. In order to prevent shock on the pipe line due to the rapid shutting off of the water, an automatic by-pass valve is provided. The valve is connected direct to the governor and is so arranged that, directly any water is shut off the turbine, the valve lifts immediately, allowing

an equal quantity of water to pass through the valve, but immediately the movement of the gate ceases the valve slowly closes without shock on the pipe line. By the arrangement, the valve anticipates any rise in pressure in the pipe line. The speed of closing is regulated by an oil cataract which can be regulated to close at any desired speed.

This type of turbine is commonly adopted for falls varying from 30 ft. to 300 ft. On the higher falls a single spiral is used, discharging its water either from one side of the wheel or from both sides.

Spiral Turbines for Small Outputs.

With a view to meet the increasing demand for small but high efficiency water turbines, *Boving & Co., Ltd.*, have designed and recently placed on the market a machine which, although low in cost, nevertheless possesses a high efficiency.

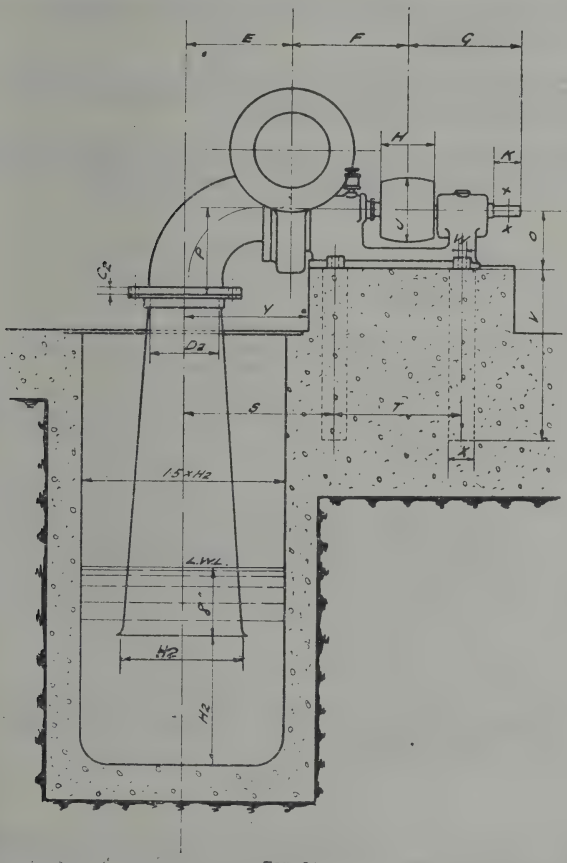

Fig. 24.

From fig. 24 it will be seen that the turbine is self-contained on its own bedplate, and consists of a specially designed spiral casing enclosing a runner of the Francis type, which is mounted on the end of the turbine shaft. The turbine is also provided with a belt pulley.

The shaft, extended at one end to accommodate a coupling, is supported on two metallic bearings, oil lubricated, and with the runner overhung; the bearings do not sustain damage should the water contain abrasive matter.

The discharge water from the runner passes through a specially designed suction bend and suction pipe into the tail race.

The foundations present no difficulties, and may be of timber blocks, steel girders, or concrete. Timber beams are frequently used with good results, as the rigid bedplate prevents the bearings from becoming out of alignment.

Another noteworthy feature is the inlet flange, which can be turned in various positions, thus simplifying the pipe line connection.

The turbine is normally arranged for the control of its speed by means of a hand-operated inlet sluice valve, but where necessary it can be equipped with the Boving patent automatic governor of the oil pressure type.

The machine described is manufactured for heads up to 60 ft., and the largest size for that head has an approximate output of 53 b.h.p. at a speed of 1,175 r.p.m. and a full-load efficiency of 82 per cent. This high efficiency was only obtained by careful design of the casing which has been evolved after a long series of tests in the laboratory.

This turbine is eminently suitable for the economical driving of mining, dairying, and similar machinery, and, owing to its unique and compact design, it can be dismantled into suitable small packages for conveyance by mule or other means where transport is difficult.

Selection of a Turbine Runner.

There are a certain number of commercial constants which are of great help to the engineer who is not a turbine designer, when attempting to select the best type of turbine to adopt for a given development and a chosen capacity per electro-generating unit.

The **Specific Speed** (N_s) is a theoretical characteristic which gives the means of comparing the relation between the conditions of speed, head and power of a runner in one installation with the same conditions relative to a runner in a totally different installation. This comparison is made after the conditions governing the design of both runners have been reduced to a common base, viz. the specific speed.

The specific speed of a runner may be defined as the speed at which any runner will run when it is reduced to such a size that it will develop one horse-power when operating under a head of unity. The numerical value, expressed in the metric system, of the specific speed of any runner may be found by first calculating the speed and power output of the runner under consideration for one metre head, and then mathematically reducing the runner in size until it will deliver one horse-power. The speed of this reduced runner when operating at its point of maximum efficiency is its rated specific speed; this speed is generally expressed in the metric system in order to adhere to an international standard. The formula is

$$N_s = 4{\cdot}45 \text{ r.p.m.} \frac{\sqrt{\text{h.p.}}}{h^{\frac{5}{4}}}$$

in which the horse-power and head are expressed in the foot-pounds system, while N_s remains in the metric system. The equivalent given in the foot-pounds system is called the 'unit speeds' or 'type characteristics.'

$$N_u = \text{r.p.m.} \frac{\sqrt{\text{h.p.}}}{h^{\frac{5}{4}}}$$

In figuring the specific speed of any reaction turbine having more than one runner, or an impulse wheel having more than one nozzle, the horse-power used in the formula, of course is the power developed by one runner only, or one nozzle only.

For a given number of revolutions per minute (r.p.m.), and head (h), the h.p. output is proportional to the square of the specific speed; also for a given head and h.p. the r.p.m. of a turbine is proportional to the specific speed.

In applying the formula for the specific speed to turbines already built it will be found that the data of an impulse wheel will give a low specific speed, between 5 and 25, while the data on the radial inward-flow turbine and on the radial inward axial flow turbine will give a high specific speed between 40 and 450. It will be noticed that there is a gap between the impulse wheel and the reaction turbine, as values of N_s between 25 and 40 do not exist with either type; but by using more than one nozzle on one impulse wheel it is possible to increase the value of N_s, so as to cover the entire field.

The formula for the specific speed contains only the two quantities, 'speed' and 'capacity for a certain head,' but as these quantities determine the areas and angles of the turbine, and thereby again the losses which take place during the passage of the water through the turbine, it will be understood that the specific speed is inherently related to the efficiency which can be expected from the turbine.

EFFICIENCY AT THREE-QUARTER POWER OF IMPULSE WHEELS.

Specific Speed.	Efficiency.
	Per cent.
5	80
9	79
13	78
18	77
22	76

EFFICIENCY OF RADIAL INWARD-FLOW TURBINES.

Type.	Specific Speed.	Maximum Efficiency.	Efficiency at half power.
		Per cent.	Per cent.
Low speed . . .	40—100	82 at 0·75 power	76
Medium speed . .	130—220	82 at 0·75 ,,	75
High speed . . .	260—360	80 at 0·80 ,,	70
Very high speed . .	400—450	73 at 0·90 ,,	53

This table shows that the different types of radial inward turbines are of different qualities. The low-speed turbines are very favourable as to efficiency over a wide range of loads, but they are practically limited to high heads. Medium-speed turbines are also very favourable as to efficiency over a wide range of loads. High-speed turbines are favourable as to efficiency at about 0·8 load, but show a marked decrease at about half load. The extreme high-speed turbines may in some cases be tolerable as to efficiency at about 0·9 load, but at about half load the efficiency is below the limit of rational utilisation of the water. The use of such turbines is only justified for low heads, with a supply of water ample in all seasons, and where the head remains rather constant.

The curve (fig. 25, p. 1390), based on tests of higher grade turbines, shows that if one desires the best efficiency possible a specific speed should be chosen between 110 and 220.

The modern practice is towards the use of large units running at the highest speed compatible with the exigencies of economical and prudent operation, so that, although the choice of a turbine depends on the power and speed desired as well as on the head available, it would seem as if the head was in most cases the deciding factor. The following table, based on this assumption, gives the type of runner desirable in function of the head.

Heads from 500′ up.	Specific speed 5 to 25.	Type of Runner Impulse Wheel.
For heads up to 500′ . .	40 to 100	Low speed, reaction.
,, ,, ,, 300′ . .	100 to 150	
,, ,, ,, 150′ . .	130 to 180	Medium speed.
,, ,, ,, 60′ . .	175 to 250	
,, ,, ,, 30′ . .	260 to 360	High speed.
,, ,, ,, 15′ . .	400 to 450	Very high speed.

EFFICIENCY CURVE.

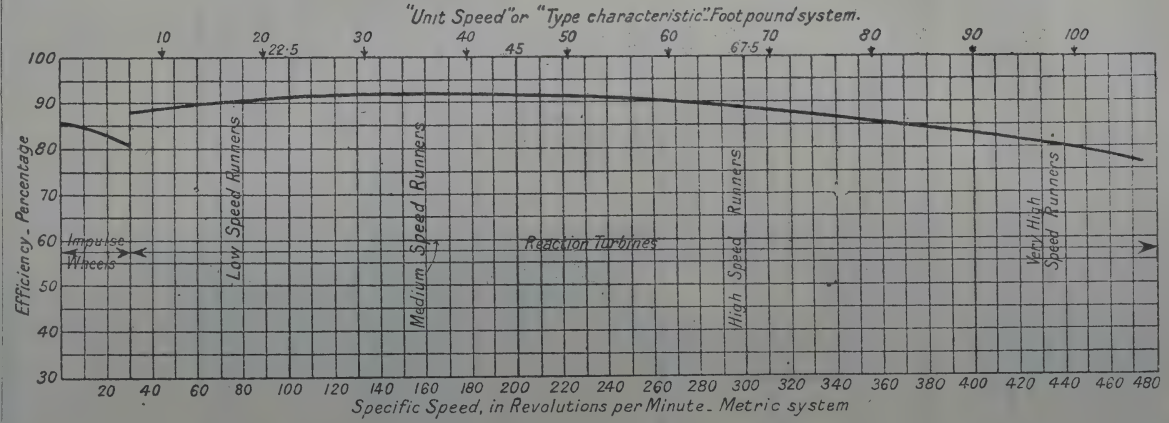

FIG. 25.

Relation between the Speed and the Discharge of a Turbine and the Head.

For maximum efficiency the peripheral speed (U_1) of any runner is a definite fraction of the spouting velocity under the given head,

$$U_1 = \phi \sqrt{2gh};$$

the best wheel speed is given by values ranging from

0·43 to 0·47 for impulse wheels,
and 0·53 to 0·57 for reaction turbines.

The discharge through a turbine is like the discharge through any orifice and varies as the square root of the head, and the coefficient of discharge has a definite value for the best value of ϕ; it follows that *the best speed and the discharge of a given turbine vary as the square root of the head* ($h^{\frac{1}{2}}$).

Relation between the Input and the Output of a Turbine and the Head.

The power available in each unit volume of water is proportional to the head, and since the quantity of water discharged varies as the square root of the head, then *the power input varies as the three-halves power of the head* ($h^{\frac{3}{2}}$).

The losses of head in any turbine vary as the squares of the various velocities concerned. Since these velocities vary as the square root of the head, their squares will vary as the first power of the head. The amount of water varies as the square root of the head, and since the power lost is the product of these two items, it follows that the *various hydraulic losses vary as the three-halves power of the head.* As the hydraulic losses vary in just the same proportion as the power input, *the hydraulic efficiency will be independent of the value of the head.*

The power output of a given turbine varies as the three-halves power of the head.

Relation between the Diameters of Stock Runners of the same Type.

When a certain type of runner has been perfected, a whole line of stock runners of that type may then be built with diameters ranging from 10 to 70 inches. All of these runners will be homologous in design, that is to say, they will have the same specific speed and each runner will simply be an enlargement or reduction of another. Having the same characteristics, that is, the same value of ϕ and c (coefficient of discharge), they will therefore follow certain laws of proportion, which can be summed up as follows for a series of runners of homologous design :

1. The best r.p.m. will be inversely proportional to the diameter.
2. The discharge of any turbine of the series will be proportional to the square of the diameter.
3. The power of any turbine of the series is proportional to the square of the diameter.

These relations are of practical value, because if the speed, discharge, and power of any runner is known by accurate test, predictions may then be made regarding the performance of any other runner of the series.

Relation between the Diameter of a Runner and its Discharge.

Since the discharge of any runner is proportional to the square of its diameter and to the square root of the head, we may write

$$q = K_1 D^2 \sqrt{h} = \text{cub. ft. per sec.}$$

The value of K_1 depends upon the velocity of the water entering the runner and the area of the passages in the runner. The velocity depends upon the value of the coefficient of discharge c, which varies from 0·6 to 0·8, and the area depends upon the diameter, the height of the runner, the angle, and also the number of buckets and guides. To summarise, the values of K_1 vary

for the tangential water wheel, from 0·0002 to 0·0005;
for the reaction turbine, from 0·0014 to 0·0360.

Relation between the Diameter of a Runner and its Power.

Since the power of any runner is proportional to the square of the diameter and to the three halves of the head, we may write,

$$\text{h.p.} = K_2 D^2 h^{\frac{3}{2}}$$

for the tangential water wheel, $K_2 = 0{\cdot}000018$ to $0{\cdot}000045$;
for the reaction turbine, $K_2 = 0{\cdot}00012$ to $0{\cdot}0033$.

Determination of the Constants.

The constants given may be computed from theory, but for practical use they should be secured from test data. The engineer who has to select a type of turbine can determine these factors by taking the information given in the catalogues of the turbine manufacturers. The tables contained in these catalogues are supposed to be made from actual tests, and give the discharge, power, and speed of runners of various diameters under various heads. Of course, as each manufacturer usually makes several lines of runners, there will be as many distinct values of the constants as he makes types of runners.

The Draft Tube.

It is generally found advantageous to install the turbine at an elevation above the elevation of the water in the tail race, but in order to do this without any loss of head it is necessary to connect the turbine discharge with the tail race water by means of an air-tight steel or concrete tube whose efflux is below the water level. This tube was formerly known as the Jonval device, but now generally called a 'Draft Tube.'

In considering the effect of the draft tube it should be remembered that a given static head may exist either wholly in the form of pressure or pressure head, or wholly in the form of vacuum or suction or draft head, or part of the head may be in the form of pressure head and the remainder in the form of draft head.

Also, a given head may exist wholly in form of pressure or static head, or wholly in the form of velocity, or part of the head may be in form of pressure and the remainder in the form of velocity, and pressure can be converted into velocity or velocity into pressure.

The effect of a draft tube on a turbine is to remove a part of the back or counter pressure due to the pressure or weight of the atmosphere, by a hanging water-column creating a partial vacuum. This water column being held in equilibrium by the pressure of the atmosphere, its height or head cannot be greater than 34 feet.

The draft head is the vertical distance between the centre of the shaft and the tail water for horizontal wheels, and between an horizontal line passing through the centre of the runner buckets and the elevation of the tail water for vertical turbines.

It is never possible to realise an effective draft head of 34 feet, as it is necessary to subtract the various losses due to the friction of the water in the draft tube, to the change in the speed of the water between the turbine runner and the lower end of the draft tube, and to the momentum or velocity still contained in the water while leaving the draft tube.

The absolute velocity in feet per second with which the water issues from the runner buckets and enters into the draft tube, assuming its diameter to be that of the outside of the runner should be from $\cdot 30\sqrt{2gh}$ to $\cdot 15\sqrt{2gh}$, and the velocity at the outlet of the draft tube may be $\cdot 1\sqrt{2gh}$, especially if the discharge is in the direction of the flow.

When no draft tube is used, the heads corresponding to the velocities of discharge from the turbine are completely lost, whilst with a properly designed draft tube it is possible to recover about 75 per cent. of the gain in head, due to the difference between the velocity head at the turbine and the velocity head at the outlet of the draft tube.

The following table gives the greatest draft-head permissible in practice, under average conditions, and for different diameters of draft tube.

Draft Head Permissible in Practice.

Diameter in feet.	Draft Head in feet.	Diameter in feet.	Draft Head in feet.
0·5	31·0	6	17·0
1·0	29·5	7	15·4
1·5	28·1	8	14·2
2·0	26·7	9	13·2
2·5	25·3	10	12·3
3·0	23·9	11	11·4
3·5	22·6	12	10·6
4·0	21·4	13	9·8
4·5	20·2	14	9·0
5·0	19·0		

The draft head given in this table is equal to the difference of elevation between the turbine and the tail water plus the velocity head corresponding to the speed with which the water leaves the draft tube.

The draft tube should be calculated to resist the atmospheric pressure, which tends to make it collapse.

Seal Rings of Hydraulic Turbines.

Water leakage between the turbine runner and the stationary casing is an important item of loss, especially where units operate at high heads. Ordinarily, labyrinth packing is employed, which causes the water to take a very circuitous path and be subjected to close clearances. Abrasive material contained in the water, however, has a disastrous effect on such metallic packing, and is the cause of objectionable repairs. Solid matter jamming in such clearances may cause the revolving parts to bind or run out of centre.

Rubber seal rings being flexible, eliminate a great deal of the trouble encountered, reducing the wear almost to a negligible amount. They are fitted to give material contact with the shaft, the water film acting as a lubricant. Rubber of the consistency of that found in the outer casing of an automobile tire has proved the most satisfactory, after a year of experimenting by the Pelton Water Wheel Co. (America).

In most cases of putting the rings in old units, the change is quite simple and involves only the removal of the existing all-metal wearing rings or sealing rings and the substitution of the rubber rings. Usually, this is done without other modification of the unit. The present construction of the seal rings, particularly for high-head turbines, requires that the rubber shall be vulcanised directly into the metal rings. When the rubber becomes worn, however, it is unnecessary to renew the metal ring section, as it can be again used for vulcanising a new rubber facing to restore the ring to its original condition. This results in a considerable saving in cost of the seal rings over that for the initial installation.

The highest head under which rubber seal rings are now used is 350 ft., but similar rings, in process of construction for the Oak Grove turbines, will operate under a head of 850 ft. The largest rubber seal rings thus far made are 5½ ft. in diameter, but plans are being developed for making seals of this type commercially for the very large diameter low-head turbines used extensively in the eastern part of the United States. This plan contemplates the manufacturing of the rubber seals in strips, which are then secured to their ring containers.

For corrosion-proof centrifugal pumps used for pumping acids and other corrosive fluids, a material called 'ceratherm,' invented by Mr. W. Hayhurst, M.Sc., has been introduced as a lining; it is stronger than fused silica or stoneware, and does not crack even when heated to redness and plunged in cold water. It is inert as porcelain to all chemicals and acids, and pumps of this material have been used for elevating nitric, hydrochloric, and sulphuric acids, hot and cold, hot ferric chloride, copper chloride, acetic acid, and various corrosive materials used in connection with explosives, collodion manufactures, and munition recovery plant. The material is homogeneous, and can be moulded to any shape required. It contains no soluble material, and is not brittle.

A great deal of benefit is said to be derived from an installation in a turbine plant of a Western industrial concern, whereby the lubricating oil in use in three 1875 k.v.a. turbo-generators is passed through 100 ft. of 2-in. copper coil, the latter being immersed in circulating cooling water from the ocean. The effect is a decrease in temperature of this oil of 40° F.

REGULATION OF TURBINES.

In many hydraulic plants, and notably in the hydro-electric plants, it is necessary that the rotating speed of the turbines should be constant, regardless of the power developed. This can be done either by a hand or by an automatic regulation of the water openings, in proportion to the power utilised. The automatic regulation is adopted in preference to the hand regulation in all important plants.

The water wheel governors are controlled by a centrifugal ball mechanism just as in the case of the steam engines, with the difference that, as the force required to move the turbine gates is large, it cannot be supplied by the centrifugal ball governors, but must be borrowed either from the hydraulic motor itself or from an exterior source.

The gates are therefore moved by a 'relay,' which is a device for transmitting energy from a source of energy independent—as to quantity—of the centrifugal governor balls but controlled by them in its application. If the relay is of 'mechanical type' the power required to operate the gates is transmitted, when needed, from the wheel by means of shafts, gears, friction-clutches, belts and pulleys, or other mechanical devices. In mechanical governors the flyballs may actuate pawls, friction gears, or other mechanical devices which will bring the relay into action.

If the relay is of the hydraulic type, it usually consists of a piston connected by some mechanical device to the gate rigging and moved by means of the hydraulic pressure of water taken from the penstock, or other source, or by oil supplied under high pressure from a reservoir. The pressure of the oil in the reservoir is maintained by compressed air supplied by power taken from the wheel itself. The oil thus used in moving the piston is exhausted into a receiver, from which it is pumped back into the supply reservoir. The hydraulic relay is commonly controlled by the ball governor through the medium of a small valve, which by its motion either admits the actuating water (or oil) directly to the cylinder or to a secondary piston controlling a larger admission valve.

Electrical methods of actuating the relays controlled by means of governor balls have been used to some extent but are not nearly so common as mechanical or hydraulic devices.

The best makes of hydraulic governors for medium and high falls will regulate the speed within the following limits, the percentage of variation being that of the mean speed :—

	Speed Variation. Per Cent.
For sudden variation of load of 25 per cent.	4
" " " 50 per cent.	6

Regulation due to Flywheel Effect.*

Flywheel effect is the capacity of a rotating mass to store or supply energy. This effect is expressed at 1 ft. radius and is equal to the moment of inertia of a mass, that is the weight by the square of the radius of gyration, or pounds feet squared. Modern alternating current generator rotors are built in the shape of a common flywheel and usually have sufficient flywheel effect to obtain satisfactory regulation. The flywheel effect of the rotating parts of a turbine varies with different types and usually is not considered, but it should be carefully considered for large low-head multiplex and large diameter impulse turbines. In smaller turbines it may be regarded simply as introducing a factor of safety.

The regulation due to any given flywheel effect can be computed by means of the formula

$$d = \frac{800{,}000 \times \text{h.p.} \times \text{T}}{\text{r.p.m.} \times \text{r.p.m.} \times \text{W}_r^2}$$

where,

d = percentage of variation in speed allowed ;
T = time of closure of governor in secs. ;
W = weight of rotating masses in lbs. ;
r = radius of gyration in ft. ;
W_r^2 = moment of inertia of the rotating masses in lbs. ft. squared.

Actually the relative change of speed (d) on account of the friction load of the turbine and generator is smaller than that given by the above formula. The effect of this friction load will vary according to the various types of turbines used, but the original formula may be modified safely as follows :—

$$d = 0{\cdot}8d.$$

Another cause which should be taken into consideration, providing the turbine is properly designed so as to give its maximum efficiency at normal or synchronous speed, is that the efficiency is reduced with either increasing or decreasing speed, which has the tendency to reduce further the relative change of speed (d).

The amount reduced varies with the type of runner, being greatest for a high-speed, high power runner, and least for a low-speed, low-power runner, since if correctly designed, and therefore following the laws of hydraulics, the change in efficiency will be greater for a high-speed than for a low-speed runner for the same per cent. of variation in speed. The formula modifying d, for this cause, is as follows :—

$$d \text{ eff.} = \frac{d_1}{1 + \frac{d_1}{\frac{n_2}{n_0} - 1}}.$$

The value of $\frac{n_2}{n_0}$ varies with the specific speed, and we have

Specific speed	60	90	130	180	220 to 280	310 to 370	400 to 460
Value of $\frac{n_2}{n_0}$	1·8	1·7	1·6	1·5	1·4	1·3	1·2

For impulse turbines 1·8 can be used as the value of $\frac{n_2}{n_0}$. To find the speed variation for any other than a full load change, the following must be considered : If T is the regulating time for the total governor stroke or 100 per cent. load of the turbine, it would appear that for 50 per cent. load or stroke, the regulating time would be $\frac{\text{T}}{2}$, and for 25 per cent, $\frac{\text{T}}{4}$, etc.

* Adapted from *Speed Regulation of Hydro-electric Plants*, by Wm. F. Uhl.

The regulating time for the total governor stroke or the governor closing time should be adopted only after a thorough study. Sensitive governing means severe wear and tear on the gates as well as increased shocks in the penstocks, and should be avoided where possible. Many lighting plants are successfully operated where it requires 20 seconds to close the gates, and while 20 seconds may be extreme, a closing time of 5 seconds is quite satisfactory for all but the most important or special plants.

Regulation of Turbines.

(Contributed by W. Gunther & Sons, Oldham.)

Regulation of turbines is of the utmost importance with electric power stations, where two or more generators have to run in parallel. Every change of load on a turbine is accompanied at the same moment by a change in speed, Z_{off}, when load is thrown off, and Z_{on}, when load is thrown on. These momentary changes of speed are disturbing to the smooth running of the plant, and it is in the greatest interest of the buyer of a turbine that the values of Z_{off} and Z_{on} should be as small as possible. In many cases certain conditions in regard to these values are asked from the turbine maker. The *momentary* changes of speed Z_{off} and Z_{on}, and the corresponding *remaining* changes in the revolutions Y_{off} and Y_{on}, which also must be as small as possible, are generally given in per cent. of the normal revolutions. If X_{off} and X_{on} denote the respective changes of load in per cent., the following conditions are suitable for average plants:—

$$\left.\begin{matrix} X_{off} \\ X_{on} \end{matrix}\right\} \text{25 per cent.,} \qquad \left.\begin{matrix} Z_{off} \\ Z_{on} \end{matrix}\right\} \text{not more than } 3\tfrac{1}{2} \text{ per cent.,}$$

if the corresponding values of Y are

$$\left.\begin{matrix} Y_{off} \\ Y_{on} \end{matrix}\right\} \text{1 per cent. at the most.}$$

Regulating stipulations can be made more or less severe according to the value of Z required. The *desired* speed change percentages are considerations for the power consumer; for the practically *obtainable* percentages the relative pipe length is, in the first instance, the deciding factor. The term 'relative pipe length' expresses the ratio: length of pipe line / head. The greater the relative pipe length, the more difficult it is to obtain satisfactory governing, and in many cases a compromise between the desired and the practically obtainable regulating percentages is the only solution.

As a general guide, the following percentages of speed variation should be obtainable:

Plant with a Good Relative Pipe Length (2 to 3).

X_{off} per cent.	X_{on} per cent.	Z_{off} per cent.		Z_{on} per cent.		Y_{off} per cent.		Y_{on} per cent.	
		Francis.	Pelton.	Francis.	Pelton.	Francis.	Pelton.	Francis.	Pelton.
25	25	2	3	2½	2½	1	1	1	1
50	50	5	5	6	6	2	2	2	2
100	100	10	12	13	—	3	3	3	3

Plant with Unfavourable Relative Pipe Length (over 3).

X_{off} per cent.	X_{on} per cent.	Z_{off} per cent.		Z_{on} per cent.		Y_{off} per cent.		Y_{on} per cent.	
		Francis.	Pelton.	Francis.	Pelton.	Francis.	Pelton.	Francis.	Pelton.
25	25	5	4½	6	5	1	1	1	1
50	50	9	8	12	9½	2	2	2½	2½
100	100	18	15	—	—	3½	3½	4	4

With respect to the current consumer two distinctions may be made:—

(1) Electric power stations which supply current for public purposes (street lighting, trams, etc.).

(2) Private industries or private power-distributing stations with mechanical or electrical power transmission between turbine and driven machinery.

In power stations of order (1) considerable instantaneous changes of load may be experienced at any time. It is therefore necessary that the turbines driving electric generators which supply current for public purposes (especially if trams or electric railways are being supplied) be so designed that they can withstand severe working conditions imposed by load changes. In plants of order (2), similar though less severe conditions obtain, and only if an accident happens is full load thrown off suddenly.

A very close relationship exists between the pipe line and the amount of flywheel effect (ΣGD^2) of the turbine, a point not often sufficiently realised by the intending purchaser. In governed plants it is important that sufficient flywheel effect be provided, and a portion at least of the necessary flywheel effect may be incorporated in the rotor of the generator. The amount of flywheel effect required is in proportion to the horse-power, the length of pipe line, and the closing time of the governor, and is inversely proportional to the square of the number of revolutions per minute of the turbine, turbine makers having their own formulæ. If a water turbine is regulated by an automatic governor, and satisfactory regulating conditions are expected, the whole mass of the rotating system must have a minimum mass moment with respect to the axis of rotation. The necessary amount of the GD^2 required is a matter to be decided by the turbine maker, because not only is the flywheel a heavy addition to the cost, but the characteristics of the governor and the efficiency of the turbine at different loads play an important part, details of which the maker only has at his disposal.

Control of Admission of Water into Reaction Turbines.

There are three different systems of regulating the amount of water supplied to the turbine in case of a variation of the load; these are (1) the cylinder gate, (2) the register gate, (3) the wicket gate.

(1) The **Cylinder Gate**, fig. 26, as its name indicates, consists of a cylinder closely fitting the guides and moving in a direction parallel to the axis of the turbine, thus decreasing or increasing

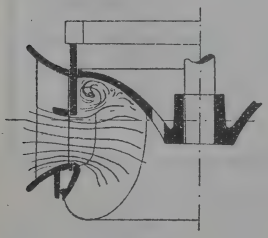

Fig. 26.—Cylinder Gate.

Fig. 27.—Register Gate.

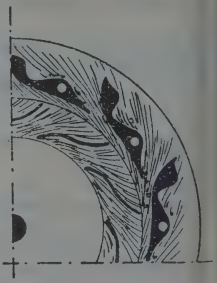

Fig. 28.—Wicket Gate.

the area left between the guide-vanes for the passage of the water. This type of gate is the simplest and cheapest but also the poorest, as the sudden contraction of the vein when passing under the partially closed cylinder gate and the sudden expansion that must take place in the bucket, produces eddying which results in decreased efficiency.

(2) In the **Register Gate**, fig. 27, the guide-vanes are made in two parts. The inner portion next to the runner is stationary, the outer portion is on a ring which may be rotated far enough

to shut the water off entirely if necessary. While this is more efficient than the preceding type, there is still a certain amount of eddying when the register gate is partially closed, with a consequent decrease in part gate efficiency.

(3) The **Wicket Gate**, fig. 28, also called the pivoted guide-vane, consists of a connection rod from the governor operating a shifting ring, which, by means of links, causes the vanes to rotate about their pivots, thus altering the area of the passages through them. This system has the working parts outside the case, which is a great advantage; its maximum efficiency is obtained before the gates are opened to the greatest extent.

Turbine Governors.

The sole efficient survivor of all the various types of governors made in the past is practically represented now by the latest forms of oil-pressure types. Oil-pressure governors as now designed are capable of giving extremely close speed regulation, the degree of regulation obtainable depending in a large measure on the hydraulic conditions under which the plant has to operate, as, although governors can be constructed which will entirely close or open the turbine gates in even as short a time as 1 second, it has been found in practice that from 2 to 3 seconds is about the maximum rate of operation which can be adopted, and even this rate is often not possible on turbines supplied through long pipe lines, owing to the dangerous water-hammer effects which would be set up. In installations of this description, relief valves can be used and quick rate of action of the governor maintained, and, on high falls, Pelton wheels provided with combined spear and deflector regulation can be successfully operated without any danger of water-hammer effects.

In practically every case it is necessary that a certain amount of flywheel effect should be provided in the plant, to assist in speed regulation and to give up or absorb power as required during the time taken by the governor to operate.

Owing to the quick rate of governor action generally adopted, it is of extreme importance that the turbine guide blades and operating gear should be of heavy and solid construction, as otherwise considerable lost motion and excessive wear will soon be set up in the gate operating gear when worked in connection with a quick-acting governor. The light construction of guide vanes and operating gear in turbines, generally known as the American type, is not suitable for obtaining efficient results and long life of working parts when used in connection with quick-acting governors.

Theoretically, speed regulation with modern quick-acting governors can be obtained to within 1 per cent. or 2 per cent. of normal with full load suddenly thrown on or off, but practical consideration of regulating gear design, governor capacity, and weight of flywheel renders such close regulation impracticable for all types of re-action turbines, although impulse turbines of the Pelton type with deflector regulation could be controlled, if necessary, within such close limits. Under ordinary conditions of power-station running, however, it is usually quite unnecessary for such fine speed regulation, and the general standard practice of governor design is to arrange for speed regulation to within 2 per cent. to 3 per cent. of normal under all ordinary working conditions, with a maximum momentary variation of 12 per cent. to 15 per cent. in the unlikely event of the whole load being suddenly thrown off.

In most standard forms of oil-pressure governors relatively small capacity oil-pumps have been used, with a reserve of power provided in the form of compressed air in the oil-receiver. This type of governor was often a source of trouble, owing to the difficulty sometimes experienced in maintaining a sufficient quantity of compressed air in the receiver, and in a number of cases to the compressed air having a detrimental effect on the oil used for operating the governor. The modern tendency is to adopt direct pumping governors without a compressed air chamber, provided with a pump of ample capacity for supplying oil to the operating cylinders at the maximum rate required.

Gilkes Oil Pressure Governor.

(Gilbert Gilkes & Co. Ltd., Kendal.)

This oil pressure governor (fig. 29) is the type constructed by Messrs. Gilkes for use on small and medium-size turbines, or in the larger sizes for controlling turbines of any power; it can equally be used for controlling Pelton wheels, but in Messrs. Gilkes' opinion the most suitable form of governor for controlling impulse wheels of any type is their patent shaft governor, with which much closer speed regulation can be obtained than is possible with the oil pressure type. The power of the shaft governor, however, is not enough to operate the gates on a reaction turbine.

The oil pressure governor is self-contained with its oil reservoir, oil pump, and speed-control mechanism. The base casting forms a reservoir for the oil, and a rotary pump is provided in this base which is driven directly from the turbine shaft.

This oil pump provides the oil pressure by means of which the governor operates the turbine gates. A separate drive is taken from the turbine shaft to operate the governor pendulum, which is of the Pickering type, and has great advantages in simplicity and sensitiveness over other types of pendulum. The pendulum operates upon a relay distributing valve which controls the direction in which the oil pressure provided by the pump will act.

In the upper part of the governor base casting a differential piston is fitted in the cylinder, so arranged that it can be operated in either direction according to whether the oil pressure from the pump is supplied to one side or the other of the cylinder. The piston is mounted on a piston rod which projects through the governor base at both ends. At one end it is fitted with a large hand wheel; the other end carries an eye and is arranged to operate the lever for moving the turbine gates. To this end of the piston rod is also secured the lever which controls the compensation mechanism of the governor. This mechanism is of the floating lever type; by a suitable adjustment the governor can be arranged to give either a small percentage drop of speed as the load comes on or a constant speed at all loads, or even a small percentage of rise in speed as the load increases.

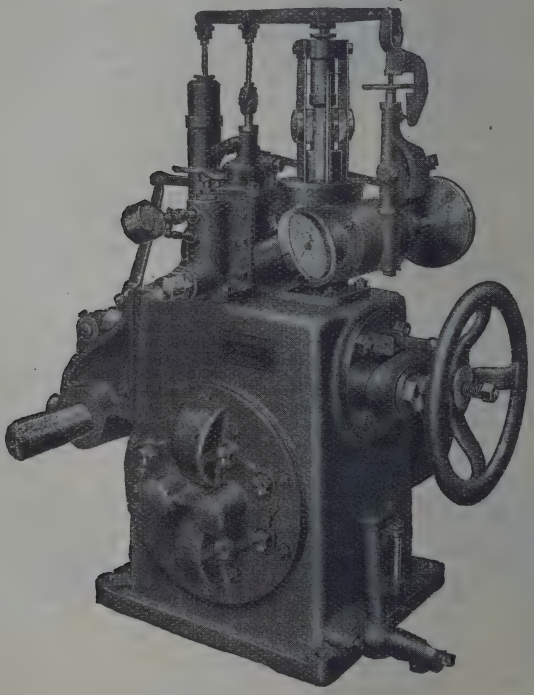

FIG. 29.

Where turbine plants have to work in parallel, the most convenient arrangement is to arrang the governor for a small drop in speed, as the load comes on, to ensure parallelism.

For isolated plants the constant speed or rise in speed characteristic is the most useful.

The governor mechanism is so arranged that the permanent speed may be varied by 5 per cent above or below normal at will while the plant is at work. The whole governor is very accessible and all bearings are of the continuously lubricated type, so that the governor may be run for long periods without stoppage.

Turgo Impulse Wheel.

(Gilbert Gilkes & Co., Ltd., Kendal, Sole Makers and Patentees.)

One of the most important developments of recent years in impulse wheel design has been the introduction by *Messrs. Gilkes* of their Turgo Impulse type. Fig. 30 shows an outside view of this wheel mounted in cast iron casing and arranged for control by Messrs. Gilkes Patent Shaft

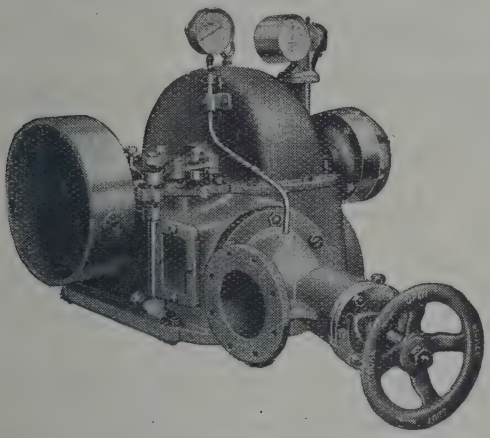

Fig. 30.—Turgo Impulse Wheel with patent Shaft Governor.

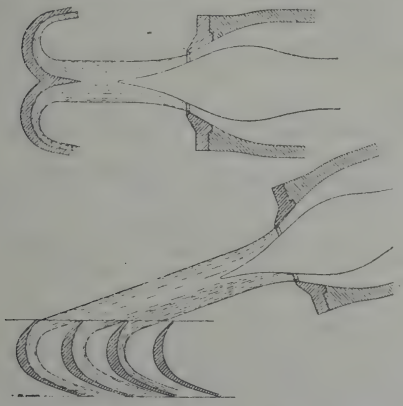

Fig. 31.—Diagram showing the difference between the principle of the Pelton and Turgo Impulse Wheels.

Governor (see p. 1375). The principle of this wheel is identical with that of the Pelton wheel in that the water gives up its power to the wheel by being freely deviated during its passage over the wheel vanes. There is no pressure in the wheel casing, and a branch pipe and nozzle piece exactly similar to that now standard with the Pelton wheel is adopted.

The difference in principle between the Turgo wheel and the Pelton wheel is clearly shown in fig. 31 (p. 1399). In the Pelton wheel the water is divided and discharged on both sides of the wheel, whereas in the Turgo wheel the water enters on one side and passes completely through the wheel and out at the other side.

The advantages claimed for the Turgo wheel are as follows :—

1. The specific speed is much higher than that of the Pelton wheel—that is to say, under given conditions of head and water quantity the Turgo wheel will run at a much faster speed than a Pelton wheel. The reason for this is that with a Pelton wheel the diameter of the jet must for best efficiency be not larger than about $\frac{1}{11}$th to $\frac{1}{12}$th of the mean diameter of the wheel. With the Turgo wheel a jet as large as $\frac{1}{5}$th of the diameter of the wheel can be efficiently applied to it.

2. The Turgo wheel is cast all in one piece with its central boss, wheel vanes, and external shrouding. It is, therefore, a strong type of construction and much more robust than the usual type of Pelton wheel with loose buckets separately bolted to a central disc. Moreover, owing to the fact that the wheel is shrouded externally, the windage and friction loss of the wheel is claimed to be very much less than that of the Pelton wheel.

TYPICAL HYDRO-ELECTRIC PLANTS.

St. Jérôme Hydro-Electric Municipal Plant on the North River, Canada.

This plant (fig. 32) was constructed in 1913 by the town of St. Jérôme to supply electricity to its population of 3,500 ; it is built on the North River, which carries the waters from the Laurentian Mountains to the Ottawa River and thence to the St. Lawrence River.

The chief features of this plant are a concrete weir, a needle dam with three openings, and a reinforced concrete pipe 8½ ft. in diameter, bringing down the water to a power house 1,000 ft. distant from the head gate. The power house consists of a semi-circular forebay of reinforced concrete communicating, by means of sluices, to the three turbine pits. These turbines are of the twin open flume type, designed to have each a maximum output of 270 h.p. at 277 r.p.m. and operating under 20-foot head. The setting of the wheels is horizontal, and they are provided each with a concrete draft tube discharging under the power house proper. The building contains the generators, which are directly connected to the turbines through a cast iron wall plate provided with a stuffing box. Two of the generating units are now installed, and their electrical equipment consists of two 150 kw., 3-phase, 60-cycle, 6,600-volt alternators. The exciters are two 10 kw. units, 120 volts, 1,150 r.p.m. belt connected to the end of the generator shaft. The power is transmitted at 6,600 volts over a transmission line 4 miles long, to a sub-station in St. Jérôme and distributed through the town on a 2,200-volt primary circuit and a 110-volt secondary circuit.

The Cedars Rapids Manufacturing and Power Co.'s Development on the St. Lawrence River, Canada.

The plant (fig. 33) of the Cedars Rapids Manufacturing and Power Co. is situated on the St. Lawrence River about 27 miles from the city of Montreal. The low water flow of the river at that point is about 170,000 cub. ft. per second, and the company has been authorised by the Government to utilise 56,000 cub. ft. per second.

The Cedars Rapids have a fall of 32 ft. in two miles, and the river is approximately 3,000 ft. wide at that point. The development consists of a head-race canal about two miles in length, formed by an outer embankment built up in the river, parallel to the flow, and an inner bank placed back from the original shore line. This head-race is from 700 to 1,200 ft. wide, and is dammed at the lower end by the power house substructure.

The present length of the power house is 667 ft., extending from the outer bank towards the shore and connected to the present shore line by a rock-filled crib dam. This crib is 48 ft. high, and so placed that the work of extending the power house for the remaining 513 ft. to the new shore line for the final development may be carried on without disturbing the crib. When the power house is ready for the final development the crib and fill may be removed by dredging.

The turbines for this development have the largest dimensions of any in the world to date (although not the highest capacity output). In the design are seen all the features of recent advances, such as (1) volute casing and draft tube moulded in the concrete substructure, (2) cast iron speed ring with the vanes serving as columns to support the concrete floor, generator and thrust-bearing loads from above, (3) lignum vitæ guide bearing, (4) Kingsbury thrust bearing located above the generator, and (5) pneumatic brakes acting on the generator rotor to bring the revolving parts quickly to a standstill.

ST. JÉRÔME HYDRO-ELECTRIC PLANT, NORTH RIVER, CANADA.

(Designed by Messrs. Surveyer & Frigon.)

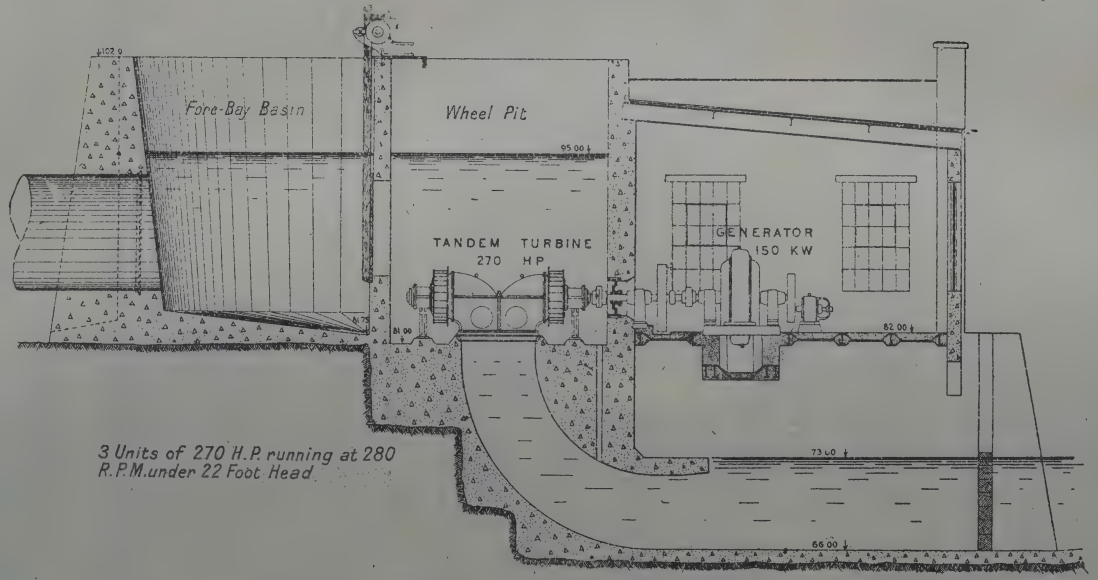

FIG 32.—Three Units of 270 h.p. running at 280 r.p.m. under 22-foot head.

The present construction provides for ten units of 10,000 h.p. each, but 160,000 h.p. will ultimately be developed.

Each generating unit consists of a vertical American turbine guaranteed to have a maximum efficiency of at least 87 per cent. when operating under an effective head of 30 ft. running

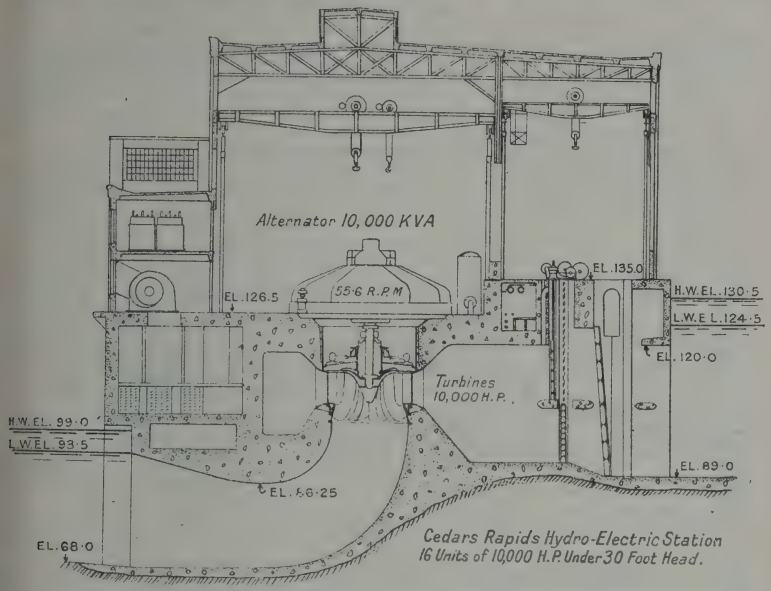

FIG. 33.—160,000 h.p. Plant on the St. Lawrence River (*Cedars Rapids Manufacturing and Power Co.*).

at a speed of 55·6 and developing between 10,000 h.p. and the maximum figure corresponding to wide open gate, provided, however, that the maximum power does not exceed 10,800 h.p. by more than 5 per cent. To each of the main turbines is connected a 10,000 kv.-a. 3-phase 6,600-volt 60-cycle generator of revolving field type.

In the transformer house on shore are the high-tension switches and feeders between transformers and transmission lines. Provision has been made for four transformer banks, two to be of 24,000 kv.-a. capacity and made up of 8,000 kv.-a. single-phase 6,600/110,000-volt units; the other two banks will be of 15,000 kv.-a. capacity, each bank having three 5,000 kv.-a single-phase 6,600/66,000-volt units. The 110,000-volt banks feed transmission lines running to Messina, N.Y., where 60,000 h.p. will be taken by the Aluminium Co. of America. The remainder of the power is transmitted at 66,000 to Montreal, from the 15,000 kv.-a. bank.

THE GRAND'MÈRE MUNICIPAL HYDRO-ELECTRIC PLANT ON THE SHAWENEGAN RIVER, CANADA.

This plant (fig. 34) was built in 1913 by the town of Grand'Mère to supply electricity to its 5,000 inhabitants. It is located at eight miles from Grand'Mère on the Shawenegan River.

The fall utilised is a hundred feet high, and the water is carried to the power house through a four-foot wood stave penstock, 1,100 ft. long.

The equipment consists of two 500 h.p. spiral casing water turbines, running at 600 r.p.m. and each directly connected to an alternating current generator and a direct current exciter. The generators are of 300 kw. capacity, producing electricity at 60 cycles and 2,200 volts. The current is stepped up, by transformers in the power house, to 10,000 volts, transmitted to a substation in Grand'Mère and distributed through the town on 2,200 volts primary circuit and a 110-volt secondary. The power-house floor is situated very high above the low water elevation of the Shawenegan River on account of the extreme high water level, due to the backing up of the St. Maurice River in the spring.

MUNICIPAL HYDRO-ELECTRIC PLANT AT GRAND'MÈRE, SHAWENEGAN RIVER, CANADA.

(Designed by Messrs. Surveyer & Frigon.)

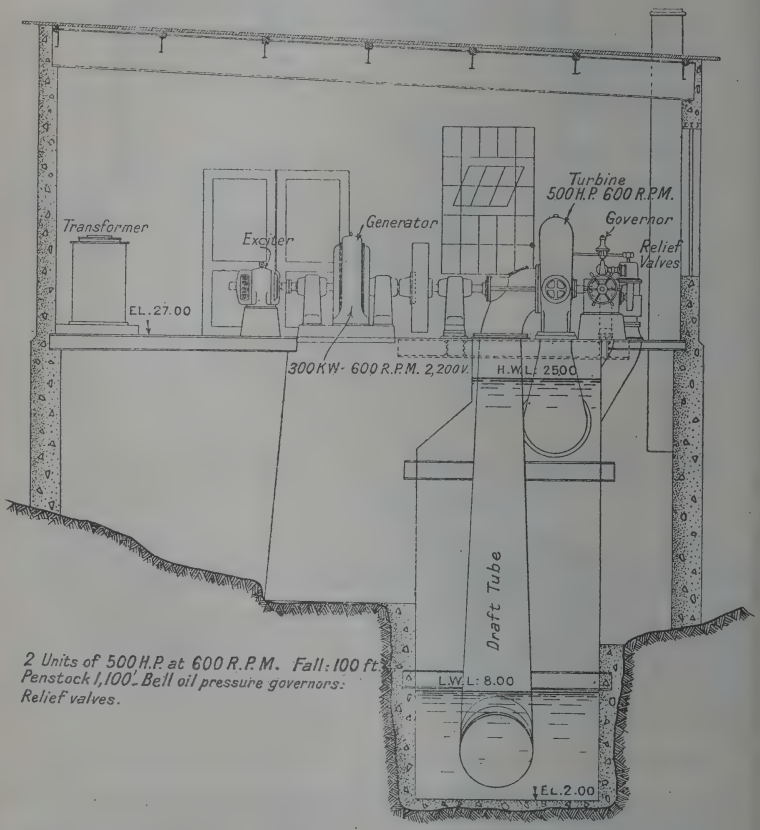

FIG. 34.

Jordan River Development of the Vancouver Island Power Company, Ltd.

The Jordan River plant (fig. 35) of the Vancouver Island Power Company, Limited, is situated at the mouth of Jordan River, which flows into the Straits of San Juan de Fuca about 40 miles west of the City of Victoria, Vancouver Island, Canada.

This development is of particular interest on account of the high head utilised, the static head at the power house being 1,145 ft. The power house is situated on the beach near the mouth of the Jordan River, with the main floor 7 ft. 6 ins. above high tide level. Water is conveyed to the water wheels in the power house from a forebay reservoir through steel pipe lines 9,290 ft. long. The forebay, which is a small equalising reservoir formed by two earth fill dams, is about 1,152 ft. above sea level, giving a static head of 1,145 ft. at the nozzles in the power house.

The power house is composed of two buildings. The first one, completed in 1911, contains two generating units of 4,000 kw. Each of these units consists of a 4,000 kw., 2,200-volt, 3-phase, 60-cycle Allis-Chalmers-Bullcok generator, driven at 400 r.p.m. by a single Doble tangential water wheel of 6,000 h.p. which is mounted on one end of the shaft and overhangs the bearing at the end of the unit.

Water is conveyed from the terminal end of the pressure pipe through a cast-steel flanged taper pipe, which is bolted to the flanged end of the pipe. This taper pipe decreases in diameter from 30 ins. to 24 ins. at the outlet end, where it is bolted to a hand-operated, 24-in., single disc, steel body, rising stem gate valve, which is provided with a by-pass. The steel nozzle casting is bolted to this valve. The jet of water is projected on to the wheel through a Doble needle regulating nozzle, and the governing is done by a type 'Q' Lombard governor, operating the needle gear by means of an oil pressure cylinder. Surges or rams in the pipe line, caused by the quick closing of the main nozzle, are prevented by the Doble relief nozzle. This nozzle is similar to the main nozzle, but is located below it, and the stream does not hit the buckets on the wheel but discharges freely down the tailrace.

The second power house was completed in 1914; it contains a third generating unit composed of an 8,000 kw., 2,200-volt, 60-cycle, 3-phase Canadian General Electric generator, driven at 400 r.p.m. by two Doble tangential water wheels, one mounted on each end of the shaft and overhanging the bearings. The water wheels are rated at 13,000 h.p.

A separate exciter unit is provided for each main generator unit. No. 1 and No. 2 exciters are 100 kw., 125-volt, direct current generators on the same shaft with a 100-h.p. water wheel and a 150-h.p., 2,200-volt induction motor. No. 3 exciter is a 200 kw. generator direct connected to a 200-h.p. water wheel and a 300-h.p., 2,200-volt induction motor.

The transformer equipment consists of two banks of 1,450 kw. transformers (with one spare) and one bank of 3,000 kw. transformers; all of the oil-insulated, water-cooled type. They step the voltage up from 2,200 to 60,000 volts, at which pressure the current is transmitted to Victoria. The transformers are set in compartments along the back wall of the generator room.

Sluice Gates, Strainer Racks, etc.

(James Gordon & Co., Ltd.)

The type of sluice-gate shown by fig. 36 is usually adopted for medium or large size head races, and is made with framing and gearing suitable for single gates up to 8 to 10 ft. wide, and for wider races, frames designed for two or more gates, according to the width of the water channel.

The frames for these gates are constructed of rolled steel joists or channels, making a very simple, cheap, and extremely strong arrangement. For smaller channels the same design and arrangement can be adopted with somewhat lighter construction, or cast-iron frames fitted with cast-iron gates and suitable lifting screws or racks can be used. Strainer racks are usually constructed of flat wrought-iron bars threaded on to rods with pipe distance-pieces placed between each bar to ensure proper spacing, the wider racks being made in s nall sections to facilitate handling.

The water channel between strainer-rack and turbine-pit should be completely covered in, in order to prevent any possibility of foreign matter getting into the channel on the turbine side of the strainer racks.

In streams which are liable to heavy floods, and contain at times a lot of drift wood and foreign matter, it is usually advisable to put down two strainer racks, the first one protecting the intake to the head race, and being made of heavy bars with wide spaces between so as to stop all the larger material, and a fine one to protect the turbines themselves at the lower end of the race close to turbine pits or pipe intakes.

In designing head and tail races for water-power installation, special attention should be paid to their cross-sectional area, which should be ample for the quantity of water to be carried, in order to guard against loss of head when the water is running at full velocity.

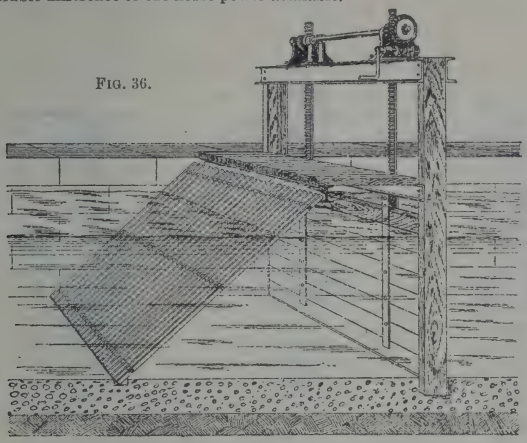
FIG. 35.

This is extremely important on plants for low falls, where only a few inches of head will make quite a considerable difference to the horse-power available.

FIG. 36.



The velocity in channels of this kind for low-fall turbine work should not exceed 2 ft. per second, and if possible should be even less than this.

For higher falls, where a slight amount of loss is not very material, velocities as high as 3 ft. or 4 ft. per second can be adopted, but care should then be taken that the banks of the channels are properly protected to prevent erosion.

NIAGARA FALLS INSTALLATION.

The cost of power supplied from the Niagara Falls is 3*l.* 6*s.* per horse-power per annum. The capital outlay on the plant was 45*l.* per horse-power.

GENERATION OF ELECTRICITY BY WATER POWER IN GREAT BRITAIN.

In the Annual Report of the Electricity Commission * it is stated that the total units generated by water power during the year ending March 31st, 1926, was 45,431,048 (from 28 stations), as against 51,093,237 (from 28 stations) in 1925.

Pipe Lines.

The following table gives thicknesses for different sizes of pipes under varying pressures. The figures are based on a factor of safety of 5, which is a fair average limit to work to for all ordinary work, but in the lower end of high-pressure pipe lines the factor of safety may run up to 8, or even sometimes 9. The working pressures are given in pounds per sq. in., and are for double-riveted or welded steel pipes; the strength of single-riveted pipes is about 30 per cent. less.

In practically every case with modern hydraulic power plants, steel piping, either riveted or welded, is used. Fig. 37, page 1408, shows types of joints which can be adopted for this class of piping. The slip joint (*a*) is suitable for low head pressures and for pipes constructed of thin

* *Generation of Electricity in Great Britain, year ending March 31st*, 1926. H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 1*s.* 6*d.* net.

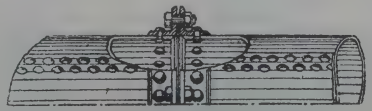
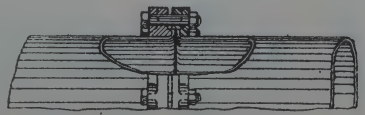
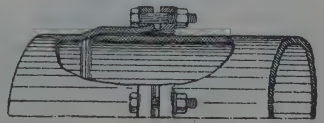
(*c*) Loose Collar Joint, packed with lead and yarn.



(*d*) Flanged Joint for riveted pipes.



(*e*) Flanged Joints for welded pipes.



(*f*) Patent Muff Joint for high pressures.

FIG. 37.

plates. The joint is made by one pipe being tapered slightly outwards and the other slightly inwards, the tapers being coated with paint, cement grout, or some similar composition, and driven into each other until they form a water-tight joint.

The socket and spigot joint (*b*) for lead and yarn packing is a very useful one for low or medium head pressures, as it has some amount of flexibility, and also allows under all ordinary conditions for any expansion or contraction in the pipes being taken up in the joints.

The collar joint (*c*) is another type of lead joint to which the same conditions practically apply.

For higher pressures ordinary forms of lead joints do not always prove satisfactory, owing to the danger of the jointing material being blown out by the pressure of the water. In these cases some form of flanged joint must be used, two of which are shown—one (*d*) with the flanges riveted on to the pipes, and the second (*e*) with the pipe ends turned up and fitted with loose flanges bolted together. The patent muff joint (*f*) is of a special type and allows for a large amount of expansion and contraction in the pipe line, and can be constructed to keep perfectly tight under the heaviest pressures which have to be dealt with.

Anchorage.—One of the most important points in the design of pipe lines is the provision for anchorage on the line itself, and especially at the foot of the line near to the power house, in order to prevent any possibility of pipe line movement being transmitted to the turbines or Pelton wheels. The pipes can be efficiently anchored in several ways, the more common forms of anchorages being to provide cast iron or steel thrust blocks, forming a foot or base on the pipe itself, which are firmly secured to heavy concrete or rock foundations; or special anchoring pipes can be provided with thrust flanges and solidly set into heavy blocks of masonry or concrete.

Expansion and *Contraction* of long lines of piping also require careful attention, and it is necessary in long straight runs of pipe to provide either a type of joint capable of taking up expansion and contraction, or to fit the pipe line with special expansion joints, which are usually constructed of cast iron or steel and of the sliding socket and spigot type.

Relief Valves.—Where the length of a pipe line is excessive in proportion to the head of water, and the plant has to deal with heavy and sudden load changes, it is necessary for the safety of the plant and pipe line to provide efficient relief valves to prevent serious water-hammer effects. These, however, should be of special design, as the ordinary forms of spring-loaded relief or safety valves are worse than useless under conditions of this kind, as if they are set to open with only a small rise in pressure the reaction of the discharging water will nearly always prevent them closing again, and if they are adjusted in the ordinary manner the pressure rises too high before they open, and the sudden closing of the valve by means of the heavy spring employed often causes worse water-hammer effects than there would be with no relief valve at all.

Relief valves for hydraulic power work should be so designed that they will open immediately with a very small rise in pressure, and in proportion to the pressure increase, the closing being effected by some form of oil cataract or dashpot which can be adjusted so that the time of closing will coincide with the time required for slowing up the moving column of water.

The best form of relief valve, however, is one which is directly connected to the gate or nozzle-operating mechanism of the power unit, and adjusted so that it will open in proportion to the decrease of gate or nozzle opening, and be closed again slowly by means of an oil dashpot or cataract. With a relief valve of this form the pressure rise is anticipated, and therefore very good results can be obtained. With a relief valve independent of the Pelton wheel or turbine rise in pressure must take place before it can come into operation.

Where Pelton wheels fitted with deflecting nozzles are used, no relief valve is generally necessary, as the quantity of water discharged remains the same for any load, or is slowly cut off by hand.

(*James Gordon & Co., Ltd.*)

Water Hammer in Pipes.

In the design of pipes (p. 1364) it was pointed out that the pipes had to be designed to resist the static head plus the head due to water hammer. The magnitude of this extra pressure depends, among other things, upon the rate of change of the velocity of the water in the pipe, and in some cases also upon the length of the pipe.

It is shown in treatises on Hydraulics that when a valve is *suddenly* closed the pressure set up due to water hammer is independent of the length of the pipe and it only depends upon the velocity of flow just before closing takes place.

Let

V = velocity of flow of water in ft. per sec.;

P = pressure set up in lb. per sq. in. due to water hammer,

then,

$$P = 63 \cdot 5\, V,$$

where the elasticity of the pipe is neglected; if the elasticity is taken into account the problem becomes rather more complicated. (See Goodman's 'Mechanics Applied to Engineering," vol. i. pp. 699–703, and vol. ii. pp. 411–413.)

The question arises—What is meant by *sudden* closing? In the references given, it is shown that when a valve is rapidly closed a compression wave traverses the pipe with a velocity of 4,720 ft. per sec., *i.e.* the velocity of sound in water. The closing is termed *sudden* if the time taken in closing the valve is equal to, or less than, the time taken by this compression wave to make the return trip of the pipe, or to traverse a distance equal to twice the length of the pipe. Thus if the length of the pipe is 6,000 ft., the time taken by the wave in traversing the pipe and returning is

$\frac{2 \times 6{,}000}{4720} = 2{\cdot}54$ seconds. The pressure due to water hammer for a velocity of 5 ft. per sec. will therefore be 317 lb. per sq. in. if the time of closing be 2·54 secs. or less.

When the valve is closed more slowly than this the pressure due to water hammer will always be less than when the closing is sudden. Many expressions have been put forward to cover this case of gradual closing, but some obviously give absurd results since they give a higher pressure for gradual than for sudden closing. Even the expressions which do not err in this particular way do not all agree, and unfortunately there are no reliable experimental data on record to act as a guide; many experiments have been made, but in every case there have been disturbing causes which have marred the value of the results. The following expression is believed to give reasonably accurate results; it being assumed that the pressure set up by gradual closing is less than that with sudden closing in the ratio:

$$\frac{\text{Pressure with gradual closing}}{\text{Pressure with sudden closing}} = \frac{Pg}{P} = \frac{Tr}{\text{Time taken in closing the valve } (Tg)},$$

where

$$Tr = \frac{2L}{4720}, \text{ L being the length of pipe in ft.};$$

then,

$$Pg = 63{\cdot}5\ V \frac{Tr}{Tg}, \text{ provided } Tg \text{ is equal to or greater than } Tr.$$

In the example given above, L = 6,000 ft.; V = 5 ft. per sec.; $Tr = 2{\cdot}54$ secs.

The pressure set up due to water hammer will be 317 lb. per sq. in. for any time of closing less than 2·54 secs.; if the valve be uniformly closed in, say, 4 secs. the pressure due to water hammer will be, approximately, $Pg = 63{\cdot}5 \times 5 \times \frac{2{\cdot}54}{4} = 200$ lbs. per sq. in., and if closed in 5 secs. it will be 160 lbs. per sq. in., and so on.

These pressures are over and above the static pressure of the water in the pipe. As a rule the pressure due to water hammer should not exceed 25 per cent. of the static pressure.

(*John Goodman, M.I.C.E.*)

SECTION XXV

PART V

HYDROSTATIC PRESS—HYDRAULIC RAMS—HYDRAULIC LIFTS—HYDRAULIC BOLT FORCERS—HYDRAULIC RIVETERS.

The Hydrostatic Press.

P = Power or pressure applied. W = the weight or resistance, in lbs.
l = length of lever, in inches or feet. l' = length of fulcrum, in inches or feet.
A = Area of ram, in square inches. a = Area of piston, in square inches.

$$\frac{Pl\,A}{l'a} = W. \qquad \frac{Wl'a}{Pl} = A. \qquad \frac{Wl'a}{Al} = P. \qquad \frac{PAl}{Wl'} = a.$$

Designing Ram Cylinders.

TO COMPUTE THE THICKNESS OF THE METAL TO RESIST A GIVEN PRESSURE.

(1.)

RULE.—Multiply the pressure per square inch in pounds by the diameter of the cylinder in inches, and divide the product by twice the estimated practical tensile resistance or *value* of the metal in pounds per square inch, and the quotient will give the thickness of the metal required.

EXAMPLE.—The pressure required is 9,000 lbs. per square inch, and the diameter of the cylinder 5·3 inches; what is the required thickness of the metal or cast iron?

$$\frac{9000 \times 5{\cdot}3}{6000 \times 2} = \frac{47700}{12000} = 3{\cdot}975 \text{ ins.}$$ The *value* of the metal is here taken at 6,000.

(2.)

The following formulæ, due to F. B. Kleinhans (*Engineering News*), will be found convenient in determining the proportions of the ram cylinders:—

$$T = \frac{P\pi D_1^2}{2000 \times 4} = 0{\cdot}0003927\,PD_1^2; \qquad T_1 = \frac{PD_2}{2(S-P)};$$

$$T_2 = \frac{D_2}{2}\sqrt{\frac{P}{S}}; \qquad T_3 = \frac{D_2}{2}\sqrt{\frac{3P}{4S}}.$$

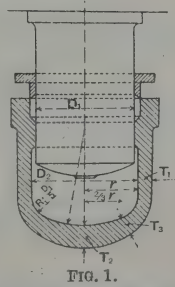


FIG. 1.

where,

T = load on rams in tons; P = water pressure in lbs. per sq. in.; S = safe fibre stress of material; D_1 = diameter of ram in inches; D_2 = diameter of cylinder in inches; T_1, T_2, T_3 = thickness of cylinder walls.

(3.)

A steel containing 0·4 per cent. of carbon is perfectly satisfactory for press, accumulator, and intensifier rams, while for pump rams a steel with a carbon content of 0·6 per cent. is generally preferred, on account of its greater hardness and durability. Stainless steel is now being extensively employed for pump rams.

Wear on the packings is considerably reduced when the ram is electro-coppered or fitted with a bronze liner, and, in consequence, the rams of machines operating at high pressures are invariably protected in this way.

In short-stroke presses the liner is carried up to a point just beyond the top of the packing—that is, almost the full length of the ram. But on long-stroke machines for baling and similar operations, where the greater part of the stroke is made at a low pressure, it is sufficient if the ram is cased for a short length only—from the end to the point at which high pressure is developed. The thickness of bronze liners varies, from $\frac{1}{4}$-in. for small rams to about $\frac{5}{8}$-in. for a ram 30 ins. diameter. The alternative to a liner is electro-coppering, the thickness of which may be anything from $\frac{1}{32}$ to $\frac{1}{8}$-in., but average requirements are met by a coating $\frac{1}{16}$-in. thick. The copper may extend just over the end of the ram or finish in a recessed joint on the wall close to the bottom. The bottom should not be coppered.

The following formula, due to Bach, for determining the thickness of the wall of a ram subjected to external pressure is in common use:

$$T = \frac{D}{2}\left(1 - \sqrt{\frac{f_c - 1{\cdot}7P}{f_c}}\right),$$

where,

T = thickness of wall in ins.; D = external diameter of ram in ins.; P = pressure in tons per sq. in.; f_c = compressive strength of material in tons per sq. in.

From this formula, a cast-iron ram 16 ins. diameter for a pressure of 2 tons per sq. in., assuming a stress of 6 tons per sq. in., gives a thickness of $2\frac{5}{8}$ ins., which is in agreement with practice.

For a ram under internal pressure the formula devised by Lamé is considered to be the most reliable.

$$T = \frac{D}{2}\left(\sqrt{\frac{f_t + P}{f_t - P}} - 1\right)$$

where,

T = thickness of wall in ins.; D = internal diameter of ram in ins.; P = pressure in tons per sq. in.; f_t = tensile strength of material in tons per square inch.

For a 16-in. ram, assuming a core diameter of 8 ins. and a stress of 2 tons per sq. in., the required thickness is 4 ins.

For low pressures and rams of small sizes the thickness of the wall as determined by the above rules, will need to be increased in order to ensure the production of generally sound and reliable castings.

A rough rule for small rams is to make the bottom flat, the end of the core semi-spherical, and the thickness at the centre equal to that of the wall. Another rule, applicable to larger rams, consists in dishing the end slightly, making the radius the same as the diameter of the ram, and the thickness about 25 per cent. greater than that of the wall.

(*Abstract of Article by H. S. C., "Machinery," January* 22, 1925.)

The Hydraulic Ram.

The water working the ram is supplied through the pipe S (fig. 2), and escapes through an opening at *o*, until it has gained a velocity sufficient to raise the valve or ball, B, which

suddenly stops the current, and causes an excessive pressure in the ram, R, which opens the valve or ball, C; the water is forced into the vessel and air-chamber, A, and finally through the delivery-pipe, *d*, to its destination. When equilibrium of pressure is restored between S and R, the ball, B, falls, and the operation is repeated. The ram can make as many as 200 strokes per minute, depending upon its size.

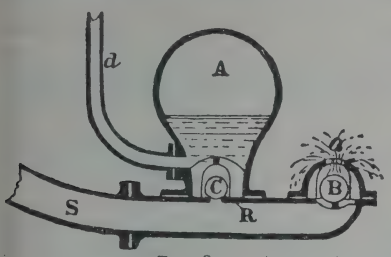

FIG. 2.

The length of the supply-pipe, S, should not be less than 5 times the height of the fall. But the pipe may be made 10 times, or more, the height of the fall.

In ordinary cases the hydraulic ram returns about 50 per cent. of the natural effect. That is, the quantity of water, *q*, multiplied by the height, *h*, of the delivery above the ram will be about 50 per cent. of the quantity of water, Q, working the ram, multiplied by the head of fall, H, in the same unit of time.

$$qh = 0{\cdot}5QF. \qquad q = \frac{0{\cdot}5QH}{h}. \qquad Q = \frac{2qh}{H}.$$

Q and *q* can be expressed in any unit of volume or weight. F and *h* can be expressed in any unit of length.

If

Q and *q* = cubic feet per minute;
F and *h* = fall and height in feet;
L = length in feet, and D = diameter in inches of the supply-pipe, S;
l = length, and *d* = diameter of the delivery-pipe, *d*,

then,

$$D = \sqrt[5]{\frac{2Q^2(L + 5D)}{F}}, \qquad d = \sqrt[5]{\frac{4q^2(l + 5d)}{h}}.$$

NOTES ON HYDRAULIC RAMS.

Working Fall.—Any working fall, from say, 18 ins. up to 100 ft., will do to work a ram, but the more the working fall obtained (up to about one-third of the total height the water has to be raised above the ram), the less the ram will cost to raise a given quantity, and the less driving water will be required to lift that quantity.

In sluggish streams where it is inadmissible to put a dam in the stream, it is sometimes necessary to carry the driving water several hundred yards down stream, in earthenware pipes running nearly level, before a few feet fall can be obtained; but where driving water is plentiful

It is often less costly to be content with a small working fall and have a more powerful ram, than to go to the expense of obtaining the greater fall, for the sake of enabling a smaller ram to do the work required.

Height to Force.—The height to force must be estimated from the level of the ram or bottom of the working fall.

Rising Main Pipe.—Rams will force to a distance of several miles. In one case a ram is in use forcing to a distance of three miles and to an elevation of 340 ft., with a working fall of only 10 ft.

Driving Water.—The quantity of driving water required to work a ram depends upon the amount of working fall available, the height to raise the water, and the quantity of water it is desired to raise. Rams can be made to work under favourable conditions with less than one gallon of water per minute.

In giving the quantity of water available to work a ram, it is useless to say there is 'sufficient to fill a pipe of certain size,' unless the gradient of the pipe be given at the same time, in order that the velocity of the water in the pipe may be ascertained. Unless the water be practically unlimited for the purpose required, it is preferable to make a positive measurement of the water. A ready method of measuring the flow of very small streams is to dam up the stream with a little puddle, and insert a pipe in the dam to form a spout. Then let the water flow into a bucket for, say, exactly 15, 30, or 60 seconds, and carefully measure out the contents of the bucket in pints, when the total flow in gallons per minute or hour can be calculated. If the stream be too large to measure with one spout, two or more spouts can be inserted in the dam, and each of them measured separately. If the ram required be a large one, and the volume of driving water available be too great to measure in this way, it should be gauged by means of a weir board.

Modern Hydraulic Rams.

Fig. 3 shows a modern form of ram.

There is a minimum ratio of lift to fall at which an ordinary ram will not work. This ratio is usually somewhere about 4 to 1.

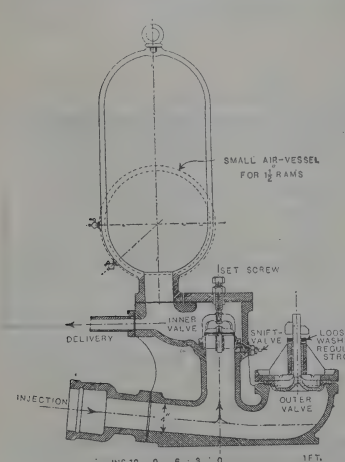

Fig. 3.

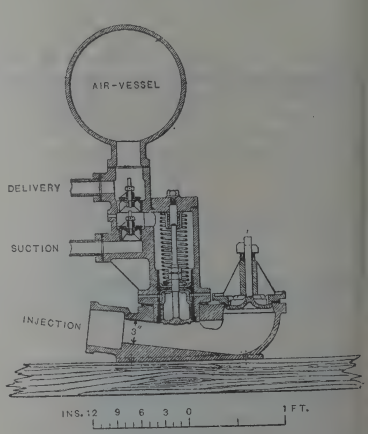

Fig. 5.

Increasing the stroke of the outer valve increases the quantity of water delivered, but reduces the efficiency, and *vice versa*.

If a ram is required to give the largest possible delivery with a limited supply of water, it is an advantage to use a large ram and give its valve a short stroke; if there is an abundance of water, it is cheaper to use a small ram with a long stroke.

A mushroom is better than a ball valve.

It has been found good practice to allow 1 sq. in. of area through the inner valve for every gallon of water to be delivered per minute. In practice a ram will not work without an air-vessel, and it must be kept properly charged with air. Certain waters in passing through the ram are found to give off air in sufficient quantity to keep the vessel charged: where, however, water has to be used which does not possess such a property, some method of supplying air must be adopted, such as a 'Snifting Valve' (p. 1265).

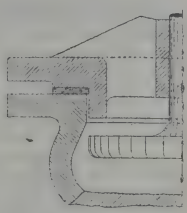

FIG. 4.

The area of the annulus between the edge of the outer valve and the body should be made rather less than that through the valve itself, so that the water should have a high speed locally and thus tend to close the valve rapidly. Fig. 4 shows the half-section of the ram body and valve, showing this contracted area.

The longer the fall pipe in relation to the fall, the better for both efficiency and capability of functioning of the ram under all ratios of lift to fall up to 24 to 1; and the shorter the pipe, the smaller the ratio above 4 to 1 at which it will work. In general it may be said that the best results are obtainable with fall pipes having a length of from 6 to 10 times the fall.

(*Anderson.*)

HYDRAULIC RAM FOR WORKING WITH DIRTY WATER.

In this type, fig. 5, water from one source of supply may be pumped by using water under a small head from another source. It is usually employed to pump clean water from a well or spring by means of dirty or contaminated water from some other source. The efficiency of the arrangement is rather low—*i.e.* from 35 to 56 per cent.

(*Anderson.*)

Hydraulic Lifts.

A speed of 200 to 400 feet per minute is usual.

For packing the ram, hat-shaped packing is preferable to the U-shaped, as it causes less friction and lasts longer. Leather packing is the best, but the most usual form is 'hydraulic' flax or hemp in stuffing boxes.

The cylinder of the lift should be absolutely plumb.

In well-constructed direct-action lifts the total friction should not be more than 5 per cent. In suspended lifts the friction varies from 15 to 20 per cent.

An air-vessel placed between the valve-box and ram cylinder will prevent any shock in the cage from the passing of the water when the valve is opened or closed, or when the water is turned into the waste-pipe.

The gear rod or rope for high-speed lifts should have a range of from 5 to 6 feet (from full pressure to full exhaust), so that the man working the lift may have proper control over it.

The cam motion opening the valve should open the latter very gradually.

The high pressure system of working hydraulic lifts is the most economical in every way, and it enables high working speed to be obtained.

Public supplies of high pressure hydraulic power are available in London, Liverpool, Hull, Manchester, Birmingham, and Glasgow.

Direct acting ram lifts are usually adopted in this country for moderate heights; the machine consists of a hydraulic cylinder having a flange cast on its upper end resting on the foundation at the top of the well bored to receive it, and a simple platform or cage moving between guides firmly screwed to the upper end of the ram working in the cylinder. The valve controlling the action of the lift is worked by a rope, or rod passing through the platform. Tappet gear automatically stops the lift at the top of its stroke, and permanent stops are also fitted to prevent overtravel. Alternative rams can be fitted to meet varying loads.

The suspended type of lift is less expensive than the direct-acting lift when the height of travel is considerable, or where there are difficulties in boring the well for the cylinder. A factor of safety of 10 to 15, to 1, on all ropes (collectively) is ample; very high factors mean, in most ordinary cases, that ropes become too large in diameter to ensure long life. The ram can be placed in the lift shaft or in the roof, or basement, either vertically, horizontally, or on an incline. Safety gear should be fitted to come into immediate action in case the ropes break. The valves are similar to those used for the direct-acting type.

The direct ram lift is becoming usual in America even in the highest buildings on account of its safety. The cylinder consists of a bored well lined with stout Artesian tubing, and failure can hardly occur, for the pipes fit closely in the bored rock. The outlet piece if well made and attached to the lining tube is not apt to fail. Balances are employed so that the long rams when out are under tension.

The guide-bars of lift should preferably be fixed to stone templates with bolts let in and secured by lead, and the bars fixed by nuts. This is preferable to wooden bricks, which are liable to shrink. The V guide-bar is the best form.

Electric push button control of lift and gates can be fitted to either type of lift.

Each elevator shaft of the 'Empire Building,' in New York, is walled up independently as high as the third floor, and is made a close fit for the car, the last 50 feet of the drop of each elevator thus forming an air-cushion. If the car fall, the air is confined in the bottom of the shaft, and, by its gradual escape, lets the elevator down easily without shock. It is stated that a car has been dropped from the twentieth floor of the building without breaking eggs placed in the car. The pressure of the air caused by a fall from the top floor, a height of 290 feet, is calculated to be about 3½ lbs. per sq. in. The estimated proportion between the depth of the air-cushion and the length of the drop is as 1 to 6. The only precaution necessary seems to be to make the doors of the lower-floor entrances air-tight.

In hydraulic lifts trouble sometimes arises owing to water leaking from the ram glands and falling on to the ropes. Where this possibility exists the ropes should be well protected with a coating of tallow and blacklead well mixed together, otherwise the water will find its way into the interior of the rope, and by rusting the wires will rapidly weaken them. The danger in such cases lies in the fact that there is often no external evidence to show that the ropes are unsafe. In one instance the two supporting ropes of a lift broke without warning near to their anchorage to the cylinder, causing the lift car to fall the full height of the lift well, wrecking the lift and killing the attendant. On examination of the broken ropes it was found that the internal wires had been damaged by the water to such an extent that they were quite brittle and without strength, but no broken wires were noticeable at the point of failure, before the accident. The best way to prevent such failures is to design the lift so that water cannot possibly fall on the ropes, or, if this be not feasible, to fit drip trays or other appliances to keep the water off the ropes if leakage should occur.

Danish Regulations concerning the Arrangement and Working of Lifts and Hoists driven by Machinery.

The lift cage must be closed in all round, except at the entrance, either with solid sides and roof or with trellis-work having openings not exceeding 1 in. It must be lit up inside, and must contain a notice of the number of passengers allowed. From any point in its travel there must be the means of signalling if in difficulty. Except where their adoption would be attended with serious inconvenience, entrance-doors must be fitted inside the cage itself; these must not open outwards, and must be kept locked while travelling. Where they are dispensed with, at every landing the lift well must be fenced to the full height on the entrance side, with no inward projection; and the clearance between the cage and the well must nowhere exceed 2 ins. In ram lifts the cage and ram must be securely joined together. A hanging cage must be suspended by at least two ropes or chains, each of which must alone be strong enough to carry ten times the weight of the cage fully loaded. Each must also be connected with either a stopping apparatus or a brake, so arranged that the cage shall either be stopped in a fall of not more than 1 ft. or else shall be let down at a speed not exceeding 3 ft. a second. Lifts worked by a winding drum must be provided with a contrivance for preventing the rope from becoming slack in the event of the cage sticking in its descent, and at the same time for stopping the drum. Every counterbalance weight is likewise to be hung by at least two ropes or chains, each having ten times the strength necessary to carry the weight. The counterbalance weights must be securely guided, and the space in which they work must be securely fenced, so as to guard against all possible risk of accident.

Hydraulic Bolt Forcers.

Fig. 6 represents Young's Hollow-ram Portable Hydraulic Bolt Forcer, constructed principally for forcing in and out coupling bolts, though it is also suitable for forcing pins, etc., in and out of machines. The apparatus consists of a hollow steel sliding ram, the ends or tails of which project through the front and back respectively of the cylinder. Inserted in this hollow ram is a steel drift, which passes right through the centre of ram; a head is forged on one end of the steel drift, and a shoe for the bolt is fitted on the other. The method of working is the same as in any ordinary hydraulic pump, viz. the fluid is forced by the pump from the reservoir into the cylinder, and the ram is gradually forced forward until it presses the shoe, on the end of the steel drift, against the bolt to be forced out. Should the bolt show no sign of moving out of coupling when the maximum hydraulic pressure has been obtained, a sharp blow is given with a hammer on the head of the drift, which transmits a shock or 'jar' to the bolt and starts it from its position, and it can then be ejected, either by pumping the ram forward or knocking it out by

hammering on the head of the steel drift; this is a valuable feature, as the bolts are generally rusted in their seats, and a sharp blow is very efficacious in starting a bolt or pin under powerful and steady pressure.

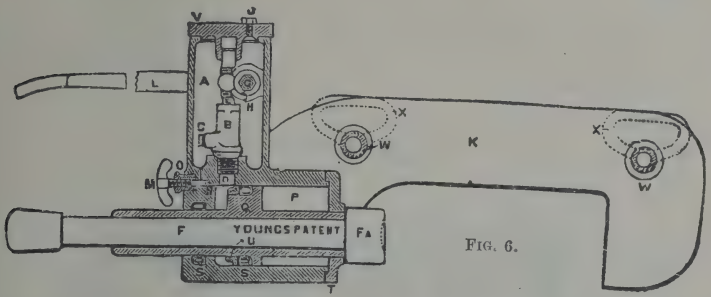

FIG. 6.

A, cistern; B, pump; C, suction valve, spring, stopper, and gauze strainer; D, delivery valve spring, and stopper; E, pump plunger; F, steel drift; F A, drift shoe; G, pump shaft; H, pump tumbler with set screw; J, air screw; K, arms; L, working pump lever; M, stop and release valve; N, stop and release seat; O, stop and release valve gland; P, cylinder; Q, hollow ram; SS, U leather for packing; T, cylinder cover; U, packing ring; V, cistern lid; W, distance pieces; X, handles.

This machine, fitted with crosshead instead of arms as shown, is largely used for forcing winch drums from their shafts.

DETAILS OF HYDRAULIC FORCERS.

Power	tons	20	20	30	40	50	75
Width of gap	inches	9	15	12	14	16	18
Run out	inches	3	3	4	5	5½	6½
Height	inches	15½	15½	16½	17	18	18½
Suitable for bolts approx. .	inches diam.	2	2	2½	3	4	5
Approx. weight	cwts.	1¾	2	3	4	4½	6¼

The body of the apparatus can be separated from the arms or claws by withdrawing two small sliding bolts, when the machine can then be carried in two separate pieces, the body placed first in position on the shaft, and the claws lifted up afterwards and fixed, without having to screw and unscrew any bolts. A gauge supplied with each machine indicates the pressure.

Hydraulic Riveters.

Fig. 7 represents the Tweddell hydraulic riveter (manufactured by Fielding & Platt, Ltd. Atlas Works, Gloucester), a tool which is very largely used for riveting purposes.

In this machine, by means of two rams, one inside the other, a pressure, in the first place, is brought to bear on the plates by means of an annular tool, A, encasing the moving capping die, B. When the plates are thus brought together, the capping tool heads the rivet; and after this operation is performed, the combined power of both rams (C and D) is applied on the head of the rivet, and through the shoulders of same on to the plate surrounding it. The size of work is only limited by the power of the machine, but some very good work in cold riveting, up to 1 inch diameter, has been done by these machines. An advantage of the machine is that by substituting a riveting die for the annular closing tool, A, a second and smaller power is available. This adds very much to the general use of the tool, for it is impossible to keep such a powerful machine in constant work. Excellent work had been done by this machine when using plain bolts—*i.e.*, making both heads of the rivet in the act of closing it. This machine is capable of exerting three different powers, which is a great advantage. Although these machines are made

up to 200 tons power, very little more high-pressure water is required, owing to the use of the auxiliary piston, E, which draws forward by means of the lug, F, the two main rams, C and D, the space left behind being filled with low-pressure water through check-valves, G and H, from a tank, J.

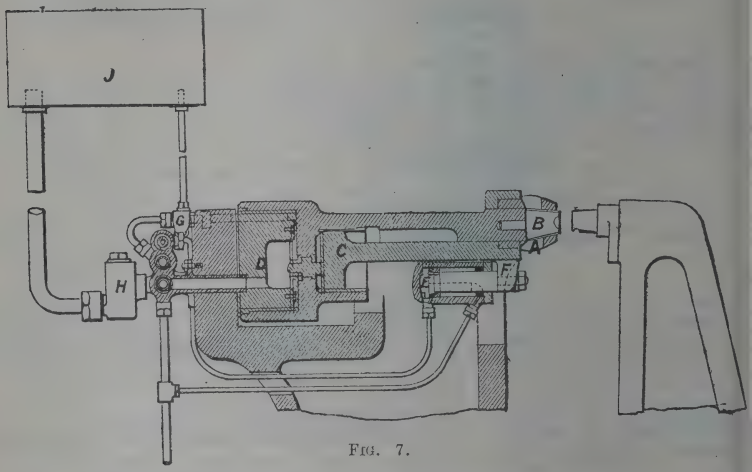

FIG. 7.

In cases where boiler-ends are placed with their flanges inwards, the machine shown by Fig. 8 is used. In this machine there is a hinged arm, A, which is first of all lowered into the boiler, and when restored to its proper position, A′, the riveting is proceeded with.

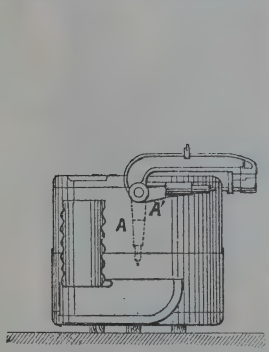

FIG. 8.

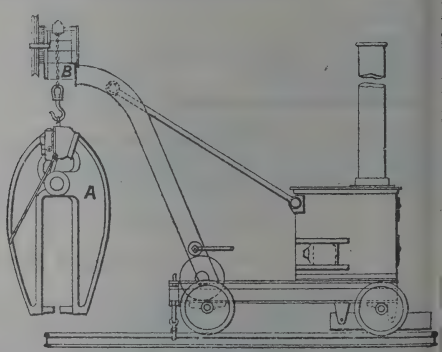

FIG. 9.

Fig. 9 shows a portable riveter, A, slung from a travelling crane. By means of the iron girder, B, this riveter is moved across the work to be riveted, whilst the crane with its rivet heating oil or reverberatory furnace is traversed along. Riveters of this type were largely used in the construction of the Forth Bridge.

SEWERS

Rate at which Rainfall Reaches a Sewer.

C = cubic feet per second per acre reaching sewer; c = average cubic feet of rainfall per second per acre during heaviest fall; S = average slope of ground in feet per 1,000 ft.; a = number of acres drained; K = ·75 for paved streets, ·625 for ordinary cases, ·31 for suburbs with gardens, lawns, and macadamised streets.

$$C = Kc\sqrt[4]{\frac{S}{a}}$$ (*Burkli-Zeigler.*)

(For other formulæ see 'Rainfall,' p. 1461.)

Discharging Capacity of Sewers.

R = hydraulic mean depth in feet; S = sine of angle of inclination; v = velocity in feet per second.

$$v = 124\sqrt[3]{R^2}\sqrt{S}$$ (*Crimp and Bruges.*)

Discharge from the Submerged Orifice of a Culvert.

D = diameter of orifice in inches; L = length of out-fall culvert in feet; W = quantity discharged in cubic feet per minute; H = head in feet.

$$D = \cdot 531\sqrt[6]{\frac{LW^2}{H}}$$ (*Eytelwein.*)

Discharge from Culverts.

The important road improvement works now in progress in the United States have shown the need for further information regarding the capacity of culverts; the more particularly because pre-existing data have been derived almost exclusively from experiments on ordinary straight-walled metal, stoneware, or concrete ducts. Of recent years, however, considerable use has been made of corrugated metal pipes, which offer a much greater resistance to the flow than straight-walled conduits. With a view, therefore, to fix the relative merits of different types of culvert, the Bureau of Public Roads of the U.S. Department of Agriculture arranged for a very comprehensive series of tests to be made at the hydraulic laboratory of the State University of Iowa, where an ample supply of water was available, as well as facilities for the accurate measurement of heads and discharges. The work was carried out under the direction of Mr. D. L. Yarnell and Professors F. A. Nagler and S. M. Woodward, and is described in detail in Bulletin No. 1 issued by the University, Iowa City, Iowa, U.S.A. (the cost of the report is one dollar). In all,

over 3,000 experiments were made, in part on pipe culverts, of concrete, vitrified clay, and corrugated metal, and in part on concrete box culverts. The pipe culverts ranged in size from 12 in. to 30 in. in diameter, and the box culverts from 2 ft. square to 4 ft. square, and, in addition, further tests were made with rectangular box culverts of other than square section. As the result of their observations the authors propose the following formulae for the discharge from pipe culverts 30·6 ft. long, with straight endwall entrances :—

Concrete pipe with bevelled lip upstream, $Q = 4{\cdot}61\ D^{2.18}\ H^{0.50}$

Vitrified clay pipe with bell end up-stream, $Q = 5{\cdot}07\ D^{2.05}\ H^{0.50}$

Concrete pipe with square-cornered entrance, $Q = 4{\cdot}40\ D^{2.09}\ H^{0.50}$

Corrugated metal pipe, $Q = 3{\cdot}10\ D^{2.31}\ H^{0.50}$

where Q = discharge in cubic feet per second ; D = diameter of pipe in ft. ; H = difference in ft. of water level between the two ends.

More general formulæ applicable to culverts of any size and length when flowing full bore are :—

Concrete pipe with bevelled lip entrance,

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1{\cdot}1 + \frac{0{\cdot}026\ L}{D^{1.2}}}}$$

Vitrified clay pipe, regular bell-end upstream,

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0{\cdot}023\ D^{1.0} + \frac{0{\cdot}022\ L}{D^{1.0}}}}$$

Concrete pipe, square-cornered entrance,

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0{\cdot}31\ D^{0.5} + \frac{0{\cdot}026\ L}{D^{1.2}}}}$$

Corrugated metal pipe,

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1 + 0{\cdot}16\ D^{0.6} + \frac{0{\cdot}106\ L}{D^{1.2}}}}$$

where A = cross-sectional area of pipe in sq. ft. ; L = length of culvert in ft.

For concrete box culverts the following formulae are proposed, in which R denotes the mean hydraulic radius :

Box culverts with rounded entrance,

$$Q = \frac{A\sqrt{2gH}}{\sqrt{1{\cdot}05 + \frac{0{\cdot}0045\ L}{R^{1.25}}}}$$

Box culverts with square-cornered entrance,

$$Q = \frac{A\sqrt{AgH}}{\sqrt{1 + 0{\cdot}4\ R^{0.3} + \frac{0{\cdot}0045\ L}{R^{1.25}}}}$$

(*Engineering*, Nov. 26th, 1926.)

Circular Sewers.

x = area of sewer ÷ the wetted perimeter ; f = inclination in feet per mile ; v = velocity of flow, in feet per minute ; a = area of flow, in square feet ; V = volume of discharge, in cubic feet per minute.

$$v = 55\sqrt{x \times 2f} \qquad V = va.$$

American Rule.

(Large Sewers.)

The following formula is used by Mr. H. R. Asserson, chief engineer of the Sewer Department of Brooklyn, for proportioning the sizes of large sewers :—

$$D = \frac{3\ \log.\ A + \log.\ N + 8}{10},$$

where,

D = diameter of sewer in inches ; A = the area drained in acres ; N = the distance in feet in which the sewer falls 1 ft.

(Small Sewers.)

For small sewers up to 18 ins. in diameter the formula is—

$$D = \frac{3\ \log.\ A + \log.\ N + 6{\cdot}8}{10}$$

Salt-Glazed Ware Pipes

Salt-glazed ware pipes may be used up to 36 ins. diameter, but above 24 ins. they are difficult to manufacture of a cylindrical shape, and brickwork or concrete is usually adopted.

British Standard Salt-Glazed Ware Pipes.*

(No. 65—1914.) (*Abstract.*)

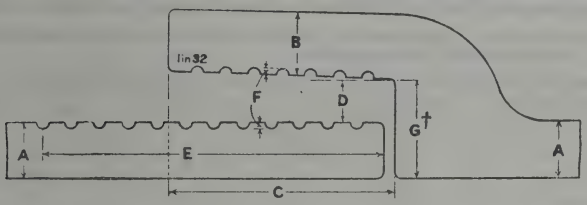
The specification divides pipes manufactured in accordance with the specification into two classes, viz. :—

British standard pipes. British standard tested pipes.

British standard pipes are pipes subject in every respect to the requirements of the specification, and a percentage are to be subjected to a hydraulic test.

British standard tested pipes are subject in every respect to the requirements of the specification, and every pipe has to withstand a hydraulic test.

The specification provides that the dimensions of pipes shall be not less than those set out in the following table, except as provided in the section dealing with permissible variation.



1	2	3	4	5	6	7
Int. Dia. of Pipe.	Minimum Mean Thickness of Barrel. A.	Minimum Mean Thickness of Socket. B.	Minimum Internal Depth of Socket. C.	Minimum Jointing Space. D.	Length of Grooving on Spigot. E=1½C.	Minimum Depth of Grooving. F.
Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	In.
3	7/16	7/16	2	5/16	3	1/16
4	1/2	1/2	2	3/8	3	1/16
5	9/16	9/16	2¼	7/16	3⅜	1/16
6	5/8	5/8	2¼	7/16	3⅜	1/16
7	11/16	11/16	2¼	7/16	3⅜	1/16
8	11/16	11/16	2½	1/2	3¾	1/16
9	3/4	3/4	2½	1/2	3¾	1/16
10	13/16	13/16	2¾	5/8	4⅛	1/16
12	1	1	2¾	5/8	4⅛	1/16
13	1 1/16	1 1/16	3	5/8	4½	1/16
14	1 3/16	1 3/16	3	5/8	4½	1/16
15	1½	1½	3	5/8	4½	1/16
18	1⅝	1⅝	3	5/8	4½	1/16
21	1⅝	1⅝	3¼	3/4	4⅞	1/16
24	1¾	1¾	3¼	3/4	5¼	1/16
27	1⅞	1⅞	3¼	3/4	5¼	1/16
30	2	2	3½	3/4	5¼	1/16
36	2½	2½	3½	1	5½	1/16

† Width of shoulder of socket, which must exceed the mean thickness of the barrel of the pipe by not less than the values for D given in column 5.

The sockets of pipes shall be conical, having a taper of one-sixteenth of an inch measured on the diameter per inch of length.

The length of the barrels of straight pipes shall be as follows :—

Up to and including 6 ins., 2 ft.

7 ins. to 10 ins. inclusive, 2 ft. and 2 ft. 6 ins.

12 ins. to 36 ins. inclusive, 2 ft., 2 ft. 6 ins., and 3 ft.

* By permission of the British Engineering Standards Association.

The interior of the sockets and exterior of the spigots shall have groove one-sixteenth inch deep for a length equalling one and a half times depth of socket.

The glazing shall be attained by the action of the fumes of volatilised common salt on the material of the pipes during the process of burning.

Subject to the mean thickness of the barrel and socket of a pipe being not less than that specified in columns 2 and 3 of the above table, a variation in the thickness of the barrel or socket may be allowed at any two points not exceeding the following :—

Diameter of Pipe.	Permissible Variation of Thickness.
Not exceeding 12 ins.	$\frac{1}{16}$ in.
13 ins. to 18 ins. inclusive	$\frac{3}{32}$ in.
28 ins. to 36 ins. inclusive	$\frac{1}{8}$ in.

The internal diameter of the barrel shall nowhere deviate from the standard diameter by more than the figure given in the following table :—

Standard Internal Diameter of Pipe.	Permissible Variation from Diameter.	Standard Internal Diameter of Pipe.	Permissible Variation from Diameter.
3 ins. and 4 ins.	$\frac{1}{8}$ in.	15 ins. and 18 ins.	$\frac{3}{16}$ in.
5 „ to 7 „	$\frac{3}{16}$ in.	21 „ and 24 „	$\frac{1}{4}$ in.
8 „ and 9 „	$\frac{1}{4}$ in.	27 „	$\frac{5}{16}$ in.
10 „ to 14 „	$\frac{5}{16}$ in.	30 „ and 36 ins.	$\frac{3}{8}$ in.
			1 in.

The permissible deviation of straightness of the barrels measured on the inside of the curve for all diameters of pipes shall be as follows :—

Length of Pipe.	Permissible Deviation from Straightness.
2 ft.	$\frac{3}{16}$ in.
2 ft. 6 ins.	$\frac{1}{4}$ in.
3 ft.	$\frac{5}{16}$ in.

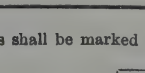
The hydraulic test shall be an internal pressure of 20 lbs. per square inch without showing signs of injury or leakage.

The pipes shall also be tested for absorption by testing pieces of the body of the pipe taken at more than 6 ins. from the end of the pipe. The test pieces shall be of whole thickness of pipe, and shall have two glazed surfaces each of which shall be not less than 8 ins. super or more than 20 ins. super. The test pieces shall be thoroughly dried at a temperature of 150°C., and shall then be immersed in cold water which shall be raised to boiling point and there maintained for one hour. The percentage of increase of weight shall not exceed the following :—

Thickness of Pipe.	Percentage of Increase of Weight.
$\frac{3}{4}$ in. and under	5 per cent.
Over $\frac{3}{4}$ in. and up to 1 in.	6 „
Over 1 in. and up to $1\frac{1}{2}$ in.	8 „
Over $1\frac{1}{2}$ in.	10 „

British standard pipes shall be marked with indelible black with the following :—

British standard tested pipes shall be marked :—



Concrete Pipes.

Sewer pipes constructed of concrete, either with or without steel reinforcement, are gaining favour amongst engineers, especially for the larger sizes of pipes and for sewers where numerous junctions are not required.

These pipes are made by several firms, and are constructed of a rich mixture of concrete with granite aggregate and the highest quality of cement. They are mostly made in moulds as plain cylinders with a curved joint made in the thickness of the concrete.

Recently the Stanton Iron Company have produced concrete pipes made by the Hume process, which is in essence a centrifugal system (see p. 1311) in which the ingredients are passed into rapidly revolving cylinders and are spread out into a uniform pipe of great density and strength. If desired, steel reinforcement can be placed in the revolving cylinders and be buried in the thickness of the concrete pipe. By this means the pipes can be greatly strengthened and can be made to carry high internal pressures.

The Hume Spun Pipes can be made in six and eight feet lengths, thus saving joints and labour in laying as compared with salt-glazed ware or ordinary moulded concrete pipes. The joints are made either by sockets spun on the pipe itself, or by loose collars used with plain cylindrical pipes. Square junctions and junctions inclined at 45° for branch drains can be supplied.

All concrete pipes above 18-in. diameter are best laid on a bed of concrete haunched up to the semi-diameter. This precaution is essential except in special circumstances with pipes of 24-inch diameter and upwards, whether the pipes are made of concrete or salt-glazed ware. Even allowing for the concrete bed, pipes made of concrete are less costly than salt-glazed ware pipes of the best qualities.

Egg-shaped Sewers.

The general form of the section of this class of sewers is shown by fig. 1.

When full.		$\frac{3}{4}$ths full.	$\frac{2}{3}$rds full.	$\frac{1}{2}$ full.	$\frac{1}{3}$rd full.	$\frac{1}{4}$ full.
Area of whole section .	$1{\cdot}1485\ d^2$	$\cdot8795\ d^2$	$\cdot7558\ d^2$	$\cdot5091\ d^2$	$\cdot2840\ d^2$	$\cdot1862\ d^2$
Perimeter of wetted surface	$3{\cdot}9649\ d$	$2{\cdot}6455\ d$	$2{\cdot}39415\ d$	$1{\cdot}8915\ d$	$1{\cdot}3746\ d$	$1{\cdot}1055\ d$
Hydraulic radius . .	$\cdot2897\ d$	$\cdot3325\ d$	$\cdot3157\ d$	$\cdot269\ d$	$\cdot2066\ d$	$\cdot1685\ d$

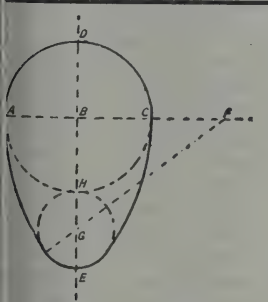


Fig. 1.

This form of sewer gives a fair hydraulic mean depth for flows varying greatly in volume. In a town sewered upon the combined system this is an advantage over the circular section, especially in the case of sewers laid in undeveloped areas where it is frequently necessary to make provision largely in excess of present requirements.

Diameter of Upper Circle = AC = d.
Conjugate Diameter = DE = $1\frac{1}{2}d$.
Radius of Invert = $\frac{1}{4}d$.
Radius of Side = FA = $1\frac{1}{2}d$.

Another advantage possessed by egg-shaped sewers is that for equal sectional areas this form is more easily entered by workmen than the circular section.

On the other hand, the egg-shaped section is not so strong to resist external pressure as the circular, and consequently if used in bad ground special precautions must be taken.

In ordinary practice, egg-shaped sewers are used for those sizes of culvert which fall between the largest circular stoneware-pipe sewers and the smallest size of circular brick culvert in which men can conveniently work.

These limits fix the maximum and minimum sizes of egg-shaped sewers at 3 ft. 6 ins. × 2 ft. 4 ins. and 2 ft. 3 ins. × 1 ft. 6 ins., respectively.

For ordinary depths the smaller sizes of egg-shaped sewers are constructed of one ring of brickwork half-a-brick thick; for the large sizes a second ring of brickwork may be introduced or, preferably, the sewer may be strengthened by placing concrete outside the brickwork.

The following table gives particulars of the ordinary sizes of egg-shaped sewers :—

Dimensions.	Sectional Area in Square Feet.		Wetted Perimeter. Lineal Feet.		Brickwork in superficial yards of half-brick thick per Lineal Yard of Culvert.	
	Total.	Up to $\frac{2}{3}$rds of top circle.	When full.	When full to $\frac{2}{3}$rds top circle.	One half-brick ring.	Two half-brick rings

The last table is applicable to sewers and drains by taking the same proportion of the tabular numbers that the cross-section of the water in the sewer or drain bears to the area of the whole area of the sewer or drain.

The formula upon which the table is constructed is :—

$$Q = 2356 \frac{\sqrt{d^5}}{\sqrt{\frac{l}{h}}},$$

where,

Q = volume of discharge, in cubic feet per minute;
d = diameter of pipe in feet;
h = height of fall of the water in feet;
l = length of pipe in feet.

Application of the Table.

To compute the volume of fluid discharged, the length of the pipe or sewer, the height or fall, and the diameter being given.

Rule.—Divide the tabular number opposite the diameter of the pipe by the square root of the rate of inclination (length ÷ height); and the quotient will give the volume required.

Example.—A pipe has a diameter of 9 ins. and a length of 4,750 feet; what is its discharge under a head of 17·5 feet?

Tabular number for 9 ins. = 1147·6, and

$$\sqrt{\frac{4750}{17{\cdot}5}} = \sqrt{271{\cdot}4} = 16{\cdot}47;$$

then,

$$\text{Discharge} = \frac{1147{\cdot}6}{16{\cdot}47} = 69{\cdot}67 \text{ cubic ft. per minute.}$$

Sewerage Systems.

There are two principal systems of sewerage, known respectively as the 'combined' and the 'separate' systems. In the former, one set of sewers is provided for the removal of both the sewage proper, and also the rainwater; in the separate system two sewers are provided in every street, one for sewage and the other for rainwater. Both systems have their advantages, but these are counterbalanced by certain disadvantages.

The combined system has the advantage of simplicity, but it involves large and deep sewers with small volumes of sewage flowing in them in dry weather, and where the sewage has to be pumped and purified this system produces a larger volume of sewage than the separate system.

On the other hand, a separate system of sewers becomes very complicated, especially in large towns, and there is great risk of sewage drains being connected to the surface water sewers. The latter discharge direct into the nearest river or stream, and can therefore be made of smaller size than in the combined sewerage system, which concentrates all liquid upon one point. The drainage of all streets and yards is taken direct into the surface-water sewers. As the first washings of these surfaces are very foul, there is danger of pollution of the streams into which the surface-water sewers discharge.

In most cases neither system is carried out in its entirety, but a combination is effected with a view to adopting the best points of both.

The quantity of sewage in a strictly separate system should, if the sewers were watertight, be measured by the water consumed, and it is usually taken at from 20 to 40 gallons per head of the population draining, and the rate of flow in the middle of the day is from one and a half times to twice the mean.

Where a partially-separate system is adopted, the back roofs and back yards of the houses are usually drained to the sewage sewers, and the impervious area per head of the population varies from 10 square yards to 20 square yards.

The rainfall on this area, at the rate of from $\frac{1}{4}$ in. to 1 in. per hour, depending upon the area of the district (being smaller for large areas than for small), must be added to the sewage, to find the discharging capacity of the sewers.

In a combined system of sewers the main factor is rainfall, and the rate of fall and proportion of impervious area and size of district must be taken into consideration in determining the dimensions of the sewers.

The proportion of rainfall flowing off an urban area probably never exceeds 75 per cent. of the gross fall, and usually 30 per cent. to 50 per cent. is sufficient to provide for in ordinary circumstances.

For discharges of catchments, including sewered areas, see 'Rainfall,' page 1461.)

As an example of practical working, the following table may be quoted, giving the basis on which sewers have for many years been designed in a North Country city with an average rainfall of 36 ins., and nearly all streets being covered with impervious paving:—

Drainage Area in Acres.	Inches of Rainfall per Hour.	Drainage Area in Acres.	Inches of Rainfall per Hour.	Drainage Area in Acres.	Inches of Rainfall per Hour.
20	1·00	75	0·47	350	0·35
23	0·95	100	0·45	375	0·34
26	0·90	125	0·44	400	0·33
29	0·85	150	0·43	425	0·32
32	0·80	175	0·42	450	0·31
35	0·75	200	0·41	475	0·30
38	0·70	225	0·40	500	0·29
41	0·65	250	0·39	525	0·28
44	0·60	275	0·38	550	0·27

50	0·50	325	0·36	600	0·25

Flushing Sewers and Drains.

All sewers and house drains should be laid at sufficiently good gradients to secure self-cleansing. To prevent deposit, 4-inch diameter drains should have a fall of not less than 1 in 40, 6-inch drains 1 in 60, and 9-inch drains 1 in 100. Whenever these gradients cannot be obtained special facilities should be provided for flushing, and this operation should be regularly attended to once or twice per week.

The water supply to closets, slop-sinks, etc., should be obtained from cisterns specially provided for the purpose, and not direct from the water-main, nor yet from cisterns in which the water for other domestic uses, such as cooking and drinking, is stored.

The best material for the cisterns is galvanised wrought-iron of No. 14 s.w.g. thickness.

The following table gives the capacities of flushing chambers for drains:—

Capacity of Flushing Chamber Required for Pipes of Different Sizes.

Size of Pipe. Diameter in Inches.	Gradient of Pipe.	Capacity of Chamber in Gallons.
4	1 in 40	30
	„ 50	40
6	„ 60	60
	„ 100	100
	„ 200	160
9	„ 100	200
	„ 150	250
	„ 200	300
	„ 300	400
12	„ 100	300
	„ 200	400
	„ 300	500
	„ 400	750
	„ 500	1,000
	„ 600	1,500

Sewers as distinguished from drains may be laid at flatter gradients than those quoted without special flushing arrangements, but this depends upon the quantity of sewage flowing down the pipe. A sewer flowing half full will maintain itself in good order at a much flatter gradient than one flowing quarter full. It is usually found that a velocity of 2 feet to 2½ feet per second will produce self-cleansing conditions.

In practical sewage works sewers with a small flow should have the following minimum gradients :—

8 ins. diam. 1 in 75.	12 ins. diam. 1 in 150.	18 ins. diam. 1 in 250.
9 ins. diam. 1 in 100.	15 ins. diam. 1 in 200.	

Where, however, the sewers have a goodly flow of sewage the following gradients will be found to be self-cleansing :—

8 ins. diam. 1 in 175.	12 ins. diam. 1 in 400.	18 ins. diam. 1 in 800.
9 ins. diam. 1 in 250.	15 ins. diam. 1 in 600.	21 ins. diam. 1 in 1,000.

Ventilation of Sewers.

The object of the ventilation of sewers is to remove the foul emanations arising from the sewage and the fouled surfaces of the sewers above the actual liquid and to discharge them at points where they will easily become diluted with fresh air and not cause a nuisance.

Until comparatively recently it was thought that sewer air was harmful in itself and was likely, not only to impair the vitality of the subject, but also to be the direct cause of infectious disease.

Now, however, it is more generally conceded that sewer air is at least as free from bacteria as the air near the surface of a road, and that apart from any offensiveness to the sense of smell it is not dangerous to persons breathing it. The degree of offensiveness of sewer air depends more largely upon the condition of the sewer than upon the effectiveness of the ventilation.

Fresh sewage does not produce a bad smell, and modern sewers constructed with the best materials and gradients and regularly flushed do not give off foul emanations. On the other hand, sewers constructed of absorbent materials, laid to bad gradients, containing deposits of sewage solids, and in which flushing is absent or carried on at very long intervals, the sewer air becomes very foul and is liable to produce nuisance.

Formerly, the generally accepted theory was that 'sewer gas,' being lighter than air, would tend to rise up the gradient of the sewer and would be discharged at its summit.

This idea has now been demonstrated to be erroneous : there are many factors which affect the motion of air in sewers such as temperature, humidity, ebb and flow of sewage, the drag of the flowing sewage, the natural diffusion of gases, friction on the periphery of the sewer, and the action of the wind.

Of all these, by far the most important is the latter, and it dominates the other factors except on very calm days.

The system of ventilation of sewers introduced on the advice of the late Sir Robert Rawlinson many years ago, was to relieve the pressure of sewer air by means of gratings in manhole covers at ground level.

These open ventilators were fixed at intervals of about 100 yds., and if it was found that some of the ventilators were a nuisance, additional openings were to be made at shorter intervals.

It has been the almost universal experience in most towns that at certain times these surface grids caused nuisance by allowing the sewer air to escape and bad smells resulted.

A modification of the system has been effected by the introduction of tall shafts connected with the sewers alternating with openings at street level.

The tall shafts theoretically act as outlets and the openings at ground level as fresh-air inlets. It is found, however, in practice, that this order is under varying conditions reversed and it is never certain which will be the inlet and which the outlet.

The general practice now is to have all manhole covers sealed where they are situated in narrow streets near the doors and windows of houses or in other situations likely to cause nuisance, and to have vertical steel or iron columns 20 to 25 ft. in height and 6 ins. to 12 ins. diameter, fixed in the line of curb and connected to the manholes to act either as inlets or outlets : the tops of the columns are fitted with wire guards.

In some cases the shafts consist of iron socketed pipes fixed against a building and carried up above the eaves or roof ridges in such a way as to be clear of all windows, skylights, or chimneys.

In broad suburban roads or where the sewers cross agricultural land, the manhole covers are still left open for ventilation purposes.

Connecting the sewers to the flues of factory chimneys has been tried but the draught is confined to a very small area and is not nearly so effective as one would anticipate. Numerous proprietary systems of sewer ventilation by means of fans, special cowls, gas destructors, antiseptic sprays and deodorants have been put on the market from time to time, but these are generally successful only in very favourable circumstances and cannot be recommended for general use.

SEWAGE TREATMENT.

Quantity of Sewage to be dealt with.

The quantity of sewage per head of the population drained, and the effect of the admission of rainwater, have been dealt with in the preceding matter dealing with sewers.

It has now become fairly well established in practice that in towns where the sewers are upon the combined system, and where the sewage is purified, the works shall be capable of providing full treatment for a quantity equal to three times the mean dry weather flow, and that in addition to this there shall be means of partially treating a further quantity equal to three times the mean dry weather flow, any surplus beyond this to be discharged untreated into the streams.

In towns sewered on the separate system the full treatment can be restricted to a volume of twice the mean dry weather flow, and partial treatment must in that case be provided for four times the dry weather flow.

Apart from the fluctuations in volume due to the admission of storm water, the quantity varies from hour to hour during the day, and in different days of the week, owing to the greater or lesser discharge of liquid from the houses in the district.

The following diagram represents the rate at which sewage is received on an average day in dry weather at the Leeds Sewage Purification Works :—

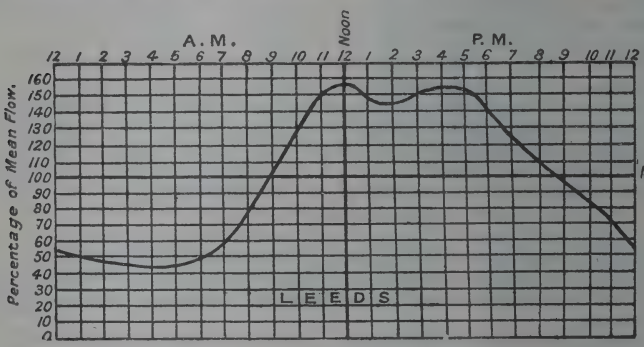

FIG. 2.

It will follow from what has been said that there are continual fluctuations in the volume of liquid to be dealt with at a sewage purification works, and such works must therefore be capable of adapting themselves to all the conditions under which they may be called upon to act.

General Outline of Treatment.

The object of all sewage purification processes is to convert the organic substances in the sewage into harmless inorganic matter. The organic matter may be in suspension or in solution, and it is not sufficient to eliminate the former, as was the case in some of the older processes, and leave the matters in solution, as these will subsequently putrefy and cause nuisance.

In average sewage of a domestic character—i.e. free from trade refuse—there are usually about 100 grains of solid matter per gallon, of which 40 grains are organic.

Grains per Gallon.	Organic.	Mineral.	Total.
Solid matter in suspension	20	10	30
Solid matter in solution	20	50	70
Total	40	60	100

The solids in suspension can be reduced by subsidence, but the matter in solution must be oxidised, and this is effected by the action of bacteria.

In all cases the first step is to remove the largest and heaviest of the suspended matters, and this is done in detritus and screening tanks.

Such tanks should have a capacity of from 2 per cent. to 5 per cent. of the daily sewage flow, and should contain iron gratings for the removal of floating matters, scum boards to arrest the scum ; and they should be so designed as to reduce the velocity of flow of sewage sufficiently to allow the heaviest of the road grit, etc., to settle to the bottom of the tank.

The next step is usually to remove the lighter matters in suspension, and this is generally effected by providing tanks of suitable design : (*a*) to allow the particles to settle by gravity ; (*b*) this process is sometimes expedited by the addition of chemicals known as precipitants; (*c*) for iquefaction of the solids in suspension by bacterial action and settlement combined, as

in septic tanks; (*d*) assisting the action by presenting large surface, to attract floating matter, as in the Travis tank or Dibdin slate filter.

Having freed the liquid as far as possible of the suspended solids with their organic contents the effluent from the first part of the process must be subjected to a further treatment, which has for its object the oxidisation of the matters in solution and their conversion into harmless inorganic compounds which will not putrefy or take up oxygen from the stream into which it may be intended to discharge them.

This part of the process may be effected by application to land or to some form of bacterial filter; but if the latter it is usually necessary to have a further process for the removal of the solids in suspension which are evacuated by the filter. This can be effected either by land treatment, filtration, or settlement in tanks or lagoons.

The capacity of the tanks necessary for the removal of the suspended solids depends upon the strength of the sewage and a variety of circumstances.

If the tank can be used for quiescent settlement—i.e. filled with sewage, allowed to stand, and then emptied by decanting—a capacity of two hours to four hours' sewage flow will usually be sufficient provision. The usual method of using such tanks, however, is to use them continuously by drawing off over a long weir in a thin film at the same rate as the filling; in such a case the tanks should have from six to twelve hours' capacity.

If, however, the settlement be assisted by the addition of precipitants, and the tanks are used for continuous precipitation, their capacity may be reduced by one-half.

Septic tanks vary in capacity from fifteen hours to twenty-four hours' flow, and there is a tendency towards the smaller limit in present practice.

Precipitation by the use of chemicals has some effect upon the organic matter in solution as well as that in suspension, and by a sufficiently large expenditure it is possible to reduce the impurity in solution by as much as 50 per cent. The cost of doing this, however, would be prohibitive in actual practice. (See table, pages 1432 and 1433.)

The precipitants chiefly used are lime in a caustic state, 10 to 12 grains per gallon of sewage; lime and sulphate of iron or green copperas in the proportion of 6 grains to 3 grains of lime with 3 grains to 1 grain of copperas; lime and alumina in the proportion of 2 of the former to 1 of the latter, usually about 8 and 4 grains respectively; alumino-ferric, either with or without lime, proportion 10 to 7 grains lime and 5 to 3 grains alumino-ferric—if used without lime, up to 8½ grains per gallon.

Sludge.

The solid matters precipitated in the tanks produce what is known as sewage sludge, containing about 90 per cent. of water.

The final disposal of the sludge resulting from sewage purification has always been one of the chief difficulties of the problem of sewage treatment. The manurial value of the material is small, and it is a waste product of the process which must be got rid of as cheaply and as expeditiously as possible.

The methods of doing this may be briefly summarised as:—

1. Removal to sea.
2. Earth burial.
3. Cremation.
4. Drying in lagoons.
5. Drying in prepared beds.
6. Filter pressing.

The quantity of sludge per million gallons of sewage varies with the quality of the sewage, and the process adopted for the separation of the solid matter therein.

The method of estimating the quantity of sludge from a given process is as follows:—

To the average number of grains per gallon of solids in suspension in the sewage add the grains of precipitant applied, and deduct from the total the grains of solids in suspension in the tank effluent; this gives the grains of solid matter deposited from each gallon of sewage.

If

G = grains per gallon as above determined;
M = sewage per day in million gallons;
T = tons of wet sludge per day (30 per cent. water);
P = percentage of water in pressed cake;
C = tons of cake containing P per cent. water;

then,

$$T = \frac{100\,M \times G}{154} \qquad C = \frac{T}{100 - P}$$

Pressed sludge cake containing 50 to 55 per cent. of water weighs about 14 cwts. per cubic yard.

Volume of sewage taken at 156,800,000 gallons per day.

(*W. J. Dibdin.*)

Land Treatment.

The effluent from the various tank processes described may be suitably oxidised by application to land.

There are two distinct methods of using land. Where a suitable light friable soil can be obtained, filtration is the process adopted, the sewage passing downward through the soil to underdrains. If, on the other hand, the available land be all of a retentive character, which will not allow of the easy passage of water, the method adopted is to pass the tank effluent over the surface of the land by irrigation and to pick it up again in suitable catchwaters and reapply it to a fresh plot, and subsequently to a third or even a fourth plot before final discharge into the stream ; such land should not be underdrained, or only to a very slight extent.

The quantity of liquid which can be dealt with per acre of land will depend upon the character of the land, the strength of the sewage, and the degree of excellence of the preliminary treatment.

The following table gives a scale of quantities for various soils and average sewage, but great care must be exercised in applying the table :—

Soil.	Crude Sewage.		Settled Sewage.		Efficient Preliminary Treatment. Land Secondary.	
	Gallons.	Population.	Gallons.	Population.	Gallons.	Population.
Light sandy loam on gravel and sand	15,000	375	20,000	500	30,000	1,000
Sandy loam on gravel and sand	12,000	300	17,000	400	30,000	1,000
Peaty soil on gravel and sand	10,000	250	13,500	325	30,000	1,000
Sand and gravel	8,000	200	10,000	250	30,000	1,000
Gravelly loam on gravel and sand	6,000	150	8,000	200	20,000	666
Loam getting more clayey	4,500	125	6,000	150	15,000	500
Heavy loam on marl	3,000	75	5,000	130	12,000	400
Clay soil on clay	1,500	50	4,000	120	10,000	333
Stiff clay soil on dense clay	1,000	33	3,000	100	10,000	333

Artificial Bacterial Methods.

The alternative to land treatment for the final or oxidising process in sewage treatment is the use of bacteria beds. These are divided into two main classes :—

(*a*) Contact beds.
(*b*) Percolating or continuous filters.

Contact beds consist of tanks filled with material such as broken clinker, and used by filling them up with tank effluent until the filtering medium is just charged with liquid, allowing it to stand for a given period, draining off, and standing empty. The usual cycle of these operations is as follows :—

Filling	1 hour.
Standing	2 hours.
Draining	1 hour.
Aerating	4 hours.
	8 hours.

With this cycle three fillings per day are possible, and as the liquid capacity of a bed is 33 per cent. of its gross capacity, it follows that a bed is capable of treating each day a quantity of tank effluent equal to its gross capacity—i.e. when containing no filtering medium. The operations of filling and emptying may be done by hand valves or by automatic valves worked by floats. The depth of contact beds should not exceed 4 ft.

The second class of bacteria beds consists of masses of hard rough material, such as broken stone or slag of gauges varying from 3 ins. to ½ in., over which the tank effluent is distributed in the form of spray and through which it percolates. The bed may or may not be enclosed by means of side walls, but it must have a good substantial floor, efficient means of drainage, and a proper system of distribution if good results are to be obtained. The depth of the beds varies from 4 ft. to 10 ft., depending upon the fall available and the size of the filtering medium.

The quantity of tank effluent which can be applied per square yard of surface of the bed depends upon the strength of the sewage and size of the material employed for filtering, and varies from 100 gallons per square yard per day to as much as 400 gallons, but this quantity cannot be maintained for long. A good average quantity is 150 gallons per square yard per day for a filter 6 ft. deep composed of materials averaging 2 ins. diameter; this will allow the bed to take the hourly fluctuations in the rate of flow of sewage, and for short periods it will take storm-water up to three times the figure named.

The sprinkling process can be effected by a variety of arrangements, most of which have revolving arms operating in different ways, but there are also fixed jets and reciprocating travellers for rectangular beds.

The relative merits of contact beds and percolating beds are as follows :—

1. Where there is not much fall available, single contact beds can be constructed with about 3 ft. 6 ins. of fall; double contact beds require 7 ft.

A continuous filter may be constructed with a fall of about 5 ft. 3 ins., but if a coarse filtering material is to be used this must be increased by 2 ft., or possibly more.

2. The tanks used for contact beds must be watertight, and therefore the facilities of the site for making watertight beds must be taken into consideration.

3. The weight of the material used in a continuous filter is greater than that of a contact bed, and therefore the stability of the ground must be taken into consideration.

4. Double contact beds must be provided if an equivalent degree of purification is required to that produced by a continuous filter.

5. Contact beds must be worked by automatic gear if three fillings per day are required, but may be operated by hand if two fillings are sufficient.

6. Generally speaking the gear for operating continuous filters is less liable to get out of order than that for contact beds.

7. Where the facilities for reducing suspended solids are limited, contact beds will sludge up and deteriorate much more quickly than continuous beds.

8. Percolating beds are more adaptable to fluctuating rates of flow than contact beds.

9. The first cost of percolating filters is less than that of contact beds for equal quantities of sewage.

10. Generally speaking, continuous filters give better results than contact beds.

Requirements of the Ministry of Health.

The following are believed to be the requirements of the Ministry with regard to sewage purification plants :—

Quantity of Sewage.

Quantity of sewage per head is usually reckoned at the rate of 30 gallons per day for dry-weather flow, for domestic purposes. In some cases this figure is modified to 20 gallons. If there be trade refuse to be dealt with, this must be added.

The quantity of sewage and rainwater to be fully treated at the works is :—

(*a*) Where the sewers are on the combined system, three times the domestic average plus $1\frac{1}{10}$ trade refuse.

(*b*) Where the sewers are on the separate system, twice the domestic sewage plus $1\frac{1}{10}$ trade refuse.

The quantity of sewage and rainwater to be partially treated is :—

(*a*) Where the sewers are on the combined system, three times the domestic sewage plus $1\frac{1}{10}$ trade refuse.

(*b*) Where the sewers are on the separate system, four times the domestic sewage plus $1\frac{1}{10}$ trade refuse.

Any excess over these quantities may be discharged over the stormwater overflows.

The above degrees of dilution are to be calculated on the average rate of flow throughout the 24 hours. The effect of this is that during the daytime when the average rate of flow is exceeded, the degrees of dilution will be less than those stated above, and on the other hand during the night the degree of dilution will be largely exceeded.

Storm Overflows.

Storm overflows on sewers should as far as is reasonably practicable be avoided, but where they are necessary they should be placed in such positions and with the weirs so fixed that no nuisance is likely to result. In any district where there is an active river authority the Ministry will desire to be informed of the opinion of such authority in respect of any proposed overflows.

In the absence of any special circumstances overflow weirs should be fixed so as not to come into operation until the flow exceeds six times that of the average dry-weather flow.

There should be no overflow for untreated sewage or stormwater at or near the disposal works.

Screens.

All liquid delivered at the disposal works should as a rule be passed through a screening chamber.

Storm-water Treatment.

A weir set at three times the dry-weather flow should be placed *below the screens*, and any volume passing over this weir should be dealt with in storm tanks. The tanks should be two or more in number and their total capacity should not be less than a quarter of the dry-weather flow. They should be so arranged that when they are full they will act as 'continuous flow' tanks, and that they can be readily emptied and kept empty when no liquid is passing into them.

The liquor from the tanks can be discharged without further treatment except in special cases, and the sludge should be dealt with by any of the usual methods which may be most suitable in the particular circumstances.

In cases where a sufficient area of suitable land is available for the purpose, detritus tanks followed by irrigation may be substituted for the storm tanks.

Sewage Treatment.

Detritus Tanks.—There should be two or more detritus tanks below the screening chamber. The capacity of each tank should be about $\frac{1}{100}$th of the dry-weather flow.

Septic Tanks.—Septic tanks should not be less than two in number, and their total capacity should be about equal to the dry-weather flow.

Chemical Preparation Tanks.—For *quiescent* treatment there should not be less than eight tanks, each of which should have a capacity equal to about two hours' dry-weather flow.

For *continuous flow* treatment there should not be less than two tanks, with a total capacity of at least eight hours' dry-weather flow, and in most cases a greater number of tanks will be desirable.

Settling Tanks.—For *quiescent* treatment—same as chemical precipitation tanks.

For *continuous flow* treatment there should not be less than two tanks with a total capacity of from ten to fifteen hours' dry-weather flow.

Filters.—In determining the sizes of percolating filters and contact beds the Ministry have, in order to allow for the strength of the sewage to be treated, adopted the division into 'strong,' 'average,' and 'weak' sewages recommended by the Royal Commission.

The strength of sewage should, when possible, be ascertained by analysing average samples of crude sewage taken in dry weather at frequent and regular intervals throughout seven days, and in proportion to the flow. Possibly, in the case of small works, the period for taking samples for analysis might be somewhat shorter, but the period should not be less than forty-eight hours, and Saturday and Sunday should be avoided. In every case, the daily rainfall during the period when the samples were being taken and during the preceding days should be ascertained.

The analysis should in all cases include the following items :—

In parts per 100,000 *by weight.*

(1) Ammoniacal nitrogen.
(2) Albuminoid nitrogen.
(3) Total nitrogen.
(4) Oxygen absorbed from strong permanganate in three minutes at 80 degrees Fahr.
(5) Oxygen absorbed from strong permanganate in four hours at 80 degrees Fahr.
(6) Suspended solids.
(7) Soluble solids.
(8) Chlorine.

It is also desirable that the amount of dissolved oxygen taken up during the oxidation of the ammoniacal and organic matter of the sewage should be given.

The results of analysis would of course require to be properly interpreted ; but as a rough guide it may be taken that from the figure for 'Oxygen absorbed from strong permanganate in four hours at 80 degrees Fahr.' the strength of the sewage may be very roughly classified as follows :—

'Strong' sewage	17 to 25 parts per 100,000
'Average" "	10 to 12 " "
'Weak' "	7 to 8 " "

In cases where the sewage cannot be analysed its strength should be estimated according to the water consumption, the flow per head, the kind of sewage system, whether water-closets are in general use, the volume and nature of trade waste, the amount of dilution by subsoil or surface water, etc.

Failing satisfactory evidence to the contrary it will be desirable to assume that the sewage is 'strong,' for the purpose of estimating the required capacity for the disposal works.

For the purpose of showing the *minimum* total cubic contents of filters required for treating three times the dry-weather flow in different cases, the tables A and B have been prepared on the data given in the Commission's Report.

The rates of filtration given by the Commission are rates which can generally be *doubled* in wet weather. Where it is proposed to deal with *three* times the dry-weather flow, the Commission say that it would generally only be necessary to provide 1½ times the capacity of filter required for the dry-weather flow. This basis has been adopted in arriving at the figure in the Tables A and B (page 1437).

TABLE A.—CONSTANTS FOR CALCULATING THE MINIMUM CUBICAL CONTENTS OF PERCOLATING FILTERS.

Preliminary Treatment.	Strong Sewage.		Sewage of Average Strength.		Weak Sewage.	
	Coarse or Medium Material.	Fine Material.	Coarse or Medium Material.	Fine Material.	Coarse or Medium Material.	Fine Material.
Detritus tanks . . .	15	*	25	*	40	*
Septic tanks	45 †	*	70	*	100	100
Settlement tanks (continuous flow) . .	45 †	*	70	*	100	100
Settlement tanks (quiescent) + ...	50 †	25	100	70	130	130
Precipitation tanks (continuous flow) . .	65	50	100	80	150	175
Precipitation tanks (quiescent)	100	65	130	130	170	200

Notes as to Filtering Material.

(*a*) A filter may be regarded as *coarse* if the material will not pass through a 1-in. sieve; as *medium* if it will pass through a 1-in. but not through a ½-in. sieve; and as *fine* if it will pass through a ½-inch sieve.

(*b*) *Coarse* material will be desirable in all cases where the liquid to be treated contains much suspended matter.

(*c*) In the cases marked * the use of fine material would not be desirable unless the circumstances were exceptional.

† If *medium* sized material were used in these cases the figures should be reduced by about 10.

TABLE B.—CONSTANTS FOR CALCULATING THE MINIMUM CUBICAL CONTENTS OF CONTACT BEDS.

Preliminary treatment.	Strong Sewage.			Sewage of Average Strength.			Weak Sewage.		
	Single Contact.	Double Contact.	Triple Contact.	Single Contact.	Double Contact.	Triple Contact.	Single Contact.	Double Contact.	Triple Contact.
Detritus tanks . . .	—	—	25 *	—	25	†	—	38	†
Septic tanks	—	—	33	—	38	†	75	66 ‡	†
Settlement tanks (continuous flow)	—	—	33	—	38	†	75 *	66 ‡	†
Settlement tanks (quiescent) .	—	—	44	—	50	†	100	†	†
Precipitation tanks (continuous flow) . . .	—	33	†	—	50	†	133 ‡	†	†
Precipitation tanks (quiescent)	—	43	†	—	66 *	†	133 ‡	†	†

Notes to Table B.

(*a*) The beds should not be less than 2 feet 6 inches nor more than 6 feet in depth.

(*b*) The different series of beds, in double and triple contacts, should have an equal cubic contents, failing any evidence to the contrary.

(*c*) Where a blank is left in the table the particular treatment indicated would only be desirable in exceptional circumstances, as the method would not generally be economical.

(*d*) In the cases marked thus †, the particular treatment indicated would only be necessary in exceptional circumstances (e.g. where an unusually good effluent is required).

(*e*) Where three times the d.w.f. has to be dealt with in wet weather, the individual beds, in the cases marked thus ‡, should be small (to facilitate rapid filling and emptying), or the total cubic contents of the filters should be increased.

(*f*) The average liquid capacity of a cubic yard of contact bed is about 50 gallons.

* There are no data in the Commission's Report with regard to these cases.

In order to ascertain the minimum total cubic contents of the filters required, divide the dry-weather flow by the *appropriate figure* (having regard to the strength of the sewage and the kind of treatment proposed), in the tables above, and the result will be the number of cubic yards which the filters should contain for treating up to three times dry-weather flow.

In cases where a sufficient area of suitable land is used for irrigating the filtrate it will probably suffice if the total cubic contents of the filters is half that provided for by the tables, but where the filter capacity is so reduced it may be necessary in wet weather to restrict the flow to the filters to about 1½ times the dry-weather flow and to pass the remainder of tank liquor direct to the land.

Effluent Tanks or Filters.—Where the effluent from filters is not irrigated on land, tanks (with a capacity equal to about two hours' dry-weather flow and with provision for removing the sludge), or shallow straining filters, will in most cases be necessary for the purpose of preventing the suspended matters in the filtrate from passing into the river.

When the sewage, after previous sedimentation, is applied to land filtration the quantity per acre of the most suitable land shall not exceed 15,000 gallons of dry-weather flow per acre per day or the sewage from 500 persons, and surplus land up to 25 per cent. is usually required to enable the land to be rested. This area will be increased, if the land be not of the first quality.

When the sewage, after previous sedimentation, is applied to land by broad irrigation, the quantity is not allowed to exceed 4,500 gallons of dry-weather flow per acre per day, or the dry-weather sewage from 150 persons. Surplus land must also be provided in such cases from 25 per cent. to 50 per cent. for resting purposes. Where the land is less suitable, the quantity per acre may be reduced to as little as 3,000 gallons per day.

When sewage is treated by precipitation or bacterial processes and the final purification is effected by land, the tank or filter effluent may be applied at the rate of 30,000 gallons per acre per day or the sewage from 1,000 persons as a maximum on the best land.

In all cases where land of sufficient area and of a not unsuitable character can be obtained at a reasonable cost the final purification must be by land.

Activated Sludge Process.

(Communicated by Activated Sludge, Ltd.)

The latest development of the sewage problem is that known as the 'Activated Sludge Process,' by which purification is carried out by oxidation of the organic matter present in the sewage by means of air blown through the liquid in the presence of an accumulation of sludge.

Experiments carried out at Manchester during 1913–14 demonstrated that by continually blowing air through successive quantities of sewage, decanting the liquid, and retaining the sludge, the latter became charged with micro-organisms which had the property of increasing enormously the purification effected by the simple aeration of the sewage. The deposit obtained in this manner has now become known as 'Activated Sludge.'

The addition of activated sludge to sewage, when combined with further blowing of fine bubbles of air through the mixture in such a manner as to create and maintain a circulation of air, sludge and liquid, sufficient to prevent settlement of the sludge and keep the sludge and air bubbles equally diffused throughout the liquid, produces a very marked change in the composition of the sewage; first a clotting or clarifying action takes place, then a rapid carbon oxidation process and finally nitrification.

Upon standing, the sludge rapidly settles and separates from the liquid, which when drawn off is not liable to putrefaction and is practically free from bacteria, whilst the sludge is also rendered innocuous and is found to contain a large proportion of nitrogen in a very available form for fertilising purposes.

It will be seen from the following table, which gives the composition of the sludge, that it has a large nitrogen content, so that its value as a fertiliser is extremely high; it contains, in fact three to four times as much nitrogen as the average septic tank sludge:—

Organic and volatile matter	64·70–70·40 per cent.
Minerals	35·30–29·60 "
Nitrogen	3·75– 7·09 "
Phosphoric acid	2·10– 4·20 "

One of the main difficulties has been to design suitable tanks, and the equipment for same, so that a regular circulation is created with a minimum expenditure of power in such a manner as to produce an equal diffusion of air and the biological sludge throughout the whole body of the

sewage in the tanks, without the creation of subsidiary eddies or deposits of sludge in pockets. This has been successfully overcome in the designs and appliances supplied by *Activated Sludge, Ltd.*, 100 *Victoria Street, Westminster, London, S.W.* 1.

A further difficulty originally was in obtaining a satisfactory settlement with a continuous flow, but, due to the researches of Mr. W. Clifford, A.M.I.C.E., of Wolverhampton, this problem was solved by a form of tank-inlet which destroys the energy of the inlet current and eddies.

The Activated Sludge Process has many advantages; the chief of these are as follows :—

(1) The purification is rapid and perfect, and the effluent fully oxidised.

(2) Putrefaction stops at once, and the system is free from smells and flies.

(3) The plant can be installed close to buildings, so that long outfall sewers are often unnecessary.

(4) An inoffensive sludge which is a valuable manure is obtained.

(5) Only a small area of land is required.

(6) There is practically no loss of head (4 ins. to 10 ins.), and the sludge is raised automatically.

(7) Trade wastes which are alkaline, or of constant but low acidity, give no difficulty.

(8) A very small staff is needed, but it requires at least one skilled attendant.

(9) Capital costs are low owing to the simplicity of the plant, the small tank area needed (less than for sedimentation or septic tanks), and the absence of filter beds. Further, by installing the plant near a town, there may be a saving in the cost of outfall sewers.

Taken all round, the cost of installing and maintaining a plant is generally about two-thirds of the cost of septic tanks and filter beds. It should be mentioned that existing tanks can usually be converted, and in many places this has been done quite successfully at small cost.

The plants work well either with a large or small population, and would appear to be well suited for military stations. There are no real disadvantages in the system except possibly the cost of power required for the intensive aeration, which is essential for the work of the process.

A great deal of attention has been devoted to the evolution of a compressor which will give a higher efficiency for the 'diffused air' system. After much thought and experiment a compressor has now been designed which effects a great saving in h.p., and this can be seen in the latest plants.

In addition to the above a great deal of thought has also been given to the production of clean air, and this problem has been solved recently.

In many places compressed air is required for raising the sewage by means of ejectors, in which case no further compressing plant is needed.

The amount of purification of the liquid sewage depends upon the period of aeration allowed, and hence with tanks of sufficient capacity it is capable of dealing with very foul sewage which would be difficult of treatment by other processes.

The entire patents for the process are held by Messrs. Activated Sludge, Ltd., 100 Victoria Street, Westminster.

Over sixty-one permanent activated sludge plant equipments for treating either sewage or trades waste have been installed by *Activated Sludge, Ltd.*, including a few now near completion. These are situated in the following countries: Great Britain, Canada, South Africa, India, Denmark, Holland, France, and Finland.

With these plants in full operation they will be treating 30,000,000 gallons of dry weather sewage, and will serve an aggregate population of 600,000.

In addition to the foregoing the Manchester Corporation have adopted this method for treating half the flow of sewage, and the scheme has been approved of by the Ministry of Health. When the plant is in full operation it will serve a population of over 300,000.

Though the 'diffused air' method has been adopted in the U.S.A. almost exclusively, these plants, which are over twenty in number, have not been included in the above, yet the four plants at Houston, Texas, Milwaukee, Indianapolis, and Chicago will treat an aggregate D.W.F. of 329,000,000 gallons per day and serve a population of 1,745,000.

As further plants have been installed and more and more data have become available from various installations, it has become possible to make comparative tests between 'ridge and furrow' and 'spiral flow' types of tanks. A definite attempt has been made to ascertain the relative values of these two forms of design in reference to weak and strong sewages with and without trades waste. Much valuable information has resulted from the many trials.

In addition, experiments have been carried out in reference to short-circuiting and the effect of increased interfacial contact on the effective capacity of these plants. These experiments have greatly added to the detailed knowledge of the requirements of the process.

The single-unit type is generally adopted for populations up to 1,000, and the double-unit type for populations up to 6,000.

A multi-unit type of not less than 4 units is used for any populations above 6,000.

The Estuary type can be used for any population, irrespective of size, and is arranged for an aeration period of a few minutes only, a high degree of purification not being required with an outfall into large rivers or estuaries, or it can be used for preliminary treatment before final treatment on filter beds.

A general description of the above types can be found in a paper read by Mr. J. A. Coombs, A.M.Inst.M.E., A.M.I.S.E., before the Institute of Sanitary Engineers in 1923.

Standard of Purity for Sewage Effluents.

The Royal Commission on Sewage Disposal appointed in 1898 put forward the following provisional standard of purity for sewage effluents for the guidance of Local Authorities.

1. That it should not contain more than three parts per 100,000 of suspended matter; and

2. That after being filtered through filter paper it should not absorb more than

(*a*) 0·5 part by weight per 100,000 of dissolved or atmospheric oxygen in 24 hours.
(*b*) 1·0 „ „ „ „ „ 48 hours; or
(*c*) 1·5 „ „ „ „ „ 5 days.

In 1913 the Royal Commission issued their 8th Report, in which they summarised their conclusions as follows:

(*a*) The law should be altered so that a person discharging sewage matter into a stream shall not be deemed to have committed an offence under the Rivers Pollution Prevention Act, 1876, if the sewage matter is discharged in a form which satisfies the requirements of the prescribed standard.

(*b*) The standard should be either the general standard or a special standard which will be higher or lower than the general standard as local circumstances require or permit.

(*c*) An effluent in order to comply with the general standard must not contain as discharged more than 3 parts per 100,000 of suspended matter, and with its suspended matters included must not take up at 65° F. (18·3° C.) more than 2·0 parts per 100,000 of dissolved oxygen in five days. This general standard should be prescribed either by Statute or by Order of the Central Authority, and should be subject to modifications by that Authority after an interval of not less than ten years.

(*d*) In fixing any special standard the dilution afforded by the stream is the chief factor to be considered. If the dilution is very low it may be necessary for the Central Authority, either of their own initiative or on application by the Rivers Board, to prescribe a specially stringent standard, which should also remain in force for a period of not less than ten years.

(*e*) If the dilution is very great the standard may, with the approval of the Central Authority be relaxed or suspended altogether. Our experience leads us to think that as a general rule, if the dilution, while not falling below 150 volumes, does not exceed 300, the dissolved oxygen absorption test may be omitted and the standard for suspended solids fixed at 6 parts per 100,000. To comply with this test no treatment beyond chemical precipitation would ordinarily be needed.

If the dilution while not falling below 300 volumes does not exceed 500 the standard for suspended solids may be further relaxed to 15 parts per 100,000. For this purpose tank treatment without chemicals would generally suffice if the tanks were properly worked and regularly cleansed. These relaxed standards should be subject to revision at periods to be fixed by the Central Authority, and the periods should be shorter than those prescribed for the general or for the more stringent standards.

(*f*) With a dilution of over 500 volumes all tests might be dispensed with, and crude sewage discharged, subject to such conditions as to the provision of screens or detritus tanks as might appear necessary to the Central Authority.

EDITORIAL NOTE.—The standards mentioned in (*e*) and (*f*) are not intended to apply to effluents discharged into streams which are used for drinking water or to streams the water of which, at the point of discharge of the sewage effluent, normally takes up more than 0·2 parts per 100,000 of dissolved oxygen in five days at 60° F. Up to the present time the proposals contained in the Report have not been embodied in any Act of Parliament, and have therefore no official authority, and must be treated as suggestions only.

HOUSE DRAINAGE.

House drains are usually made of salt glazed ware pipes varying from 3 ins. to 6 ins. diameter. Drains taking the discharge of water-closets should not be less than 4 ins. diameter.

Wherever possible all house drains should be laid outside the building; they should be laid as far as practicable in straight lines with easy bends, furnished with inspection chambers, and should be arranged so that they may be easily got at in case of necessity.

When it becomes imperative that drains should pass under the buildings, cast-iron pipes should be used and they should be laid in a straight line between two inspection chambers outside the building

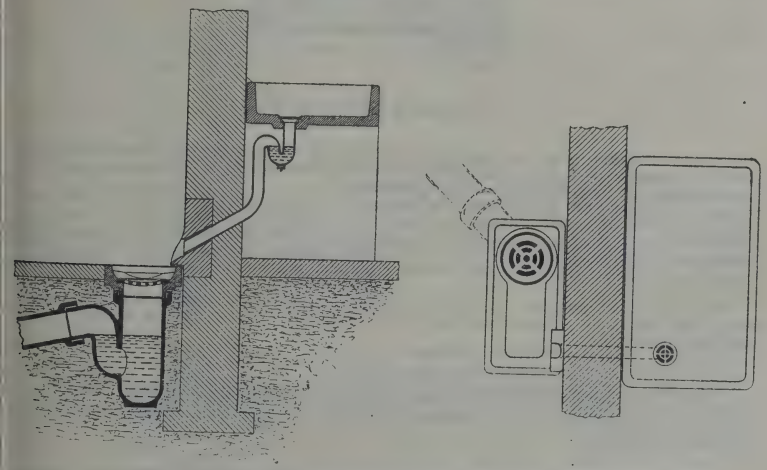

FIG. 3.—Section and Plan of Scullery Sink, with connection to Gully.

The size of drain-pipes should be sufficient to carry off sewage at the rate of forty gallons per head of the maximum population drained in six hours, and in addition rainfall at the rate of ½ in. per hour upon the area of roofs and paved yard surfaces draining to the sewers.

It was formerly considered essential that all private drains should be trapped from the sewer at a point as near as possible to the junction with the sewer, and that an inspection chamber should be built at the trap and should be provided with a fresh-air inlet.

The Local Government Board appointed a Departmental Committee to advise upon the desirability of fixing these intercepting traps near the sewers. In 1912 the Committee made their report, and stated that the case for the necessity of the intercepting trap had broken down, and that it is not only unnecessary but in many cases is harmful. It is probable, therefore, that there will be an early modification of building regulations in most towns, deleting the byelaws requiring intercepting traps between sewer and drain.

The recommendation of the Committee must not be understood to imply the uselessness of traps other than the main intercepting trap: it is just as important as ever that all inlets to drains should be trapped between the drain and the house.

The general scheme of drain trapping should be based upon the following lines:—The main drain to each house or building should be carried from the sewer without a trap or air inlet to the furthest point where a branch connection is to be made, and there a ventilating shaft should be erected and carried up well above the eaves of the house and clear of all windows, dormers, skylights, and chimneys. The end of the pipe should be fitted with a wire guard; most cowls are useless.

Branch drains for sink wastes, bath wastes, and rain-water pipes should terminate with trapped glazed stoneware gullies placed at ground-level and paved round with a containing curb of blue brick on edge on three sides and a short paved channel at least 18 ins. long on the

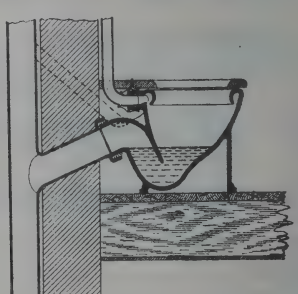

FIG. 4.—Section of Water-closet.

other on to which the waste etc. pipes should discharge. Bath wastes etc. from upper floors should be made to discharge in the open air into the cistern heads of down-pipes which are themselves cut off from the gully as above described.

Branch drains for soil pipes should be untrapped at the foot of soil pipes, and the latter should be carried up outside the external walls of the building in a straight line to above the eaves to form a ventilating column, the same precautions being adopted as in the case of the ventilation column for the end of the drain. Where there is only one soil-pipe connection it can often be arranged at the end of the main drain and so avoid the provision of more than one ventilation shaft.

When it is found inevitable that soil-pipes should be fixed inside buildings they should be of drawn lead throughout their entire length and should be carried up through the roof to give thorough ventilation.

Sinks and water-closets should, whenever practicable, be placed against external walls so that they may discharge at once into a drain outside the main wall, as shown in figs. 3 and 4.

Water-closets are best placed where they can be thoroughly ventilated directly from the external air with windows extending to the ceilings, and they should be arranged to be entered from a well-ventilated ante-room or passage with doors to shut off communication with the other portions of the house.

LONDON COUNTY COUNCIL REGULATIONS FOR WATER-CLOSETS (*Abridged*).

Building (for closet) must have one external wall abutting on a space 100 ft. square super (or if in a basement approached directly from an opening at least 5 ft. wide and 40 ft. square super) and must not be directly approached from a room used for habitation, work, storage, or preparation for food. Walls abutting on such rooms must be of brick from floor to ceiling.

A window opening directly into the external air at least 2 ft. square, and in addition at least one ventilating air brick, air shaft, or other effectual means of ventilation must be provided.

Floor of closets approached from the external air to be of hard impervious material, having a fall to the door of half inch to the foot.

Door with proper fastening to be provided.

Cisterns giving an adequate and effectual flush must be fitted to all closets. Closet cisterns must be entirely separate from cisterns containing drinking water. A proper supply of water to the cistern must be supplied. No service pipe may be allowed to be connected in any way with any part of the closet apparatus except the cistern. Downpipe and union between closet and cistern must have internal diameter of not less than 1¼ in.

Closet Basin and Trap.—The basin must be of non-absorbent material of such shape that a sufficient quantity of water is held in such a manner that the soil falls direct into the water clear of the sides.

No container to be fitted under basin.

An efficient syphon trap must be fitted immediately behind or in connection with the basin. The trap must be constructed to always provide a sufficient water-seal between the basin and the drain. Traps must be ventilated where more than one closet is connected with the same soil pipe. Ventilating pipe must not be less than 2 ins. internally, and connect with the arm of soil pipe not less than 3 ins. nor more than 12 ins. from the highest part of the trap. Ventilation must be on the drain side of the water-seal, and the ventilation pipe must be carried either to the open air at a point as high as the top of the soil pipe or to the soil pipe above the highest closet.

No D trap or similar trap must be fitted.

Soil pipe must be outside buildings wherever practicable. Soil pipes inside buildings must be drawn head with wiped joints, or heavy cast iron with molten lead joints, properly caulked. Pipe to be continued without diminution and as straight as possible to a height to allow of safe outlet by open end for foul air. Height must be above highest part of roof of building, and where practicable 3 ft. above any window that lies within 20 ft. measured in a straight line from open end. Wire guard to be fitted to open end, the area of the opening in which must be equal to not less than size of pipe.

Soil pipe must not directly connect with waste of bath, rain-water pipe, or to a sink, and soil pipe must have no trap in it nor between it and the drain.

Joints.

Lead Pipe to Iron.—A brass thimble to be used—the lead wiped to open end and the other connected with the iron by a joint of molten lead, properly caulked.

Stoneware to Lead.—Brass socket or thimble wiped to lead and connected to stoneware with Portland cement.

Stoneware to Iron.—Stoneware to be inserted into socket in iron and connected with joint made with Portland cement.

Dimensions and Weights of Soil Pipes.

Internal diameter must not be less than 3½ inches.

Diameter.	Lead. Weight per 10 feet Length not less than	Iron. Weight per 6 feet Length not less than
3½ inches.	65 lbs.	48 lbs.
4 ,,	74	54 ,,
5 ,,	92 ,,	69 ,,
6 ,,	110 ,,	84 ,,

General Notes.

Water-closet basins are all made with traps attached, and this is sufficient protection against sewer air coming into the house from the soil pipe. To ensure proper ventilation of the branch pipe from the w.c. trap to the soil pipe and to prevent unsealing by syphonic action where closets are placed over one another and are connected to the same soil pipe, a small auxiliary ventilation pipe should be connected near the trap and be carried upwards at an angle of about 45° into the soil pipe, as shown in fig. 4.

Water-closet basins should be so designed as to present as large a surface of water as possible into which the excreta may fall when the closet is in use; they should have flushing appliances which effectually wash the whole of the internal surface of the basin with the minimum of water and they should have all parts easily accessible for cleansing by hand. Closets with a syphonic action are most effectual and much to be preferred to any type of valve closets. The pedestal type of closet with lift-up lid so that it can be used as a urinal is the one most in favour.

Water-closets should be fitted with waste-preventing water-cisterns of not less than 2-gall. capacity and a 3-gall. cistern if allowed by the local waterworks regulations is preferable.

Flush pipes should be of lead or copper and should be 2 ins. diameter with a head of 6 ft. to give efficient flushing.

Urinals should not be provided at all inside private houses, and whenever they are fixed inside a building they should be made throughout of glazed stoneware with curved surfaces and as few joints as possible so as to avoid any angles in which the urine can lodge. They should be fitted with lead or copper sparge pipes capable of thoroughly washing all the surfaces liable to be soiled with urine.

Slate urinals may with advantage be painted with a mixture of common coal tar and naphtha; they should be thoroughly washed out at least once a day. Slate is not a material to be recommended for the construction of urinals; all stalls and basins should be of glazed stoneware.

The usual allowance of water for each stall in a public urinal is half a gallon per minute. The waste pipes for each stall should be 2 ins. in diameter.

White glazed bricks are preferable for facing the walls of public urinals; ordinary brick walls cemented over and painted are decidedly objectionable. The joints in the brickwork must not be thick under any circumstances, as they would present an absorbent surface.

Baths and housemaids' sinks should be of glazed porcelain fitted with trapped waste pipes which should be carried through the nearest external wall and be made to discharge in the open air over the cistern head of a downpipe: the top of the cistern head should be covered with a copper wire guard to keep out the birds, dead leaves, etc.

Kitchen and pantry sinks should be of glazed stoneware and should be fixed against an external wall, and their trapped lead waste-pipes should be carried through the wall and be made to discharge in the open air upon a paved channel leading to a trapped gully.

PART II

IRRIGATION — AVAILABLE SUPPLY — EVAPORATION — ABSORPTION—EVAPORATION FROM SOILS—LOSSES FROM IRRIGATION CANALS — MEAN VELOCITIES — CRITICAL VELOCITY—DUTY OF WATER.

Contributed by Reginald Ryves, Assoc.M.Inst.C.E., M.Cons.E.

(Author of 'A Note on Mass Dams and Dams of Arches,' etc.)

IRRIGATION.

Available Supply of Water.

Irrigation from Large Rivers.—The discharges of the river during the seasons when the water will be required are calculated from the observed depths over weirs, from differences of water level above and below bridge openings, and by the methods hereafter to be described under 'Capacities of Canals.' Whether these supplies will be fully available or not may depend upon the water levels which can be maintained above the weir, and upon what cultivable areas are commanded by the water at these levels. In this respect the scheme must be considered as a whole, and by making suitable regulations as to the crops which may be grown on certain areas and at certain seasons the availability of the supply may be increased.

Supplies from Defined Catchments.—In the case of a supply from a defined catchment the estimates of run-off may be made by the methods described under 'Rainfall,' the necessary deductions being made when the whole of the water stored cannot be directly utilised. Out of the whole recorded range of annual or seasonal rainfalls, and corresponding runs-off, one will be chosen as that suitable as a basis for the project, and the capacity of the reservoir designed accordingly. A table drawn up for catchment areas in Nagpur, Central Provinces, India (*Strange*), gives estimated yields for monsoon rainfalls ranging from 1 in. to 60 ins., and from this table the following examples are taken.

MONSOON RAINFALLS AND ESTIMATED RUNS-OFF FOR NAGPUR.

Evaporation from a Water Surface.

The actual rate of evaporation from the surface of a pool of water depends mainly on four factors: the temperature of the water itself; the velocity of the wind; the degree of humidity of the air; and the temperature of the air. As regards the first, this is more or less proportional to the air temperatures if we are measuring evaporation over considerable periods of time in different places. As regards the second, the velocity of the wind, this factor does not as a rule vary so much as others if we take a period such as a year; but it sometimes varies a great deal within areas of moderate extent, and it should be taken into consideration in making estimates of evaporation. The degree of humidity varies very greatly, not only in different countries or different districts, but also in proportion to the distance from the sea and, in some cases, with

elevation. There may be a marked decrease in the humidity of the air in a distance of a few miles from a long, straight coast line, the decrease being more gradual as we pass farther inland. There are also sharp differences between places just within and those just without the path of a monsoon current. The relation between water temperature and the rate of evaporation was studied at four stations in California (*Fortier*) with the following results, the evaporation being in sixty-fourths of an inch per day. The tanks used were of galvanised iron, 22 ins. in diameter and 28 ins. deep sunk in the ground.

Water Temperature and Evaporation.—53°F., 6; 62°F., 12; 73°F., 23; 80°F., 31; 88°F., 39.

The following were the results of experiments to test the rates of evaporation in air currents of different velocities, that in still air being taken as unity. (*Russell.*)

Wind Velocity and Evaporation.—Velocity 0, evaporation 1·00; velocity 5 miles an hour, evaporation 2·2; velocity 15, evaporation 4·9; velocity 20, evaporation 5·7; velocity 25, evaporation 6·1; velocity 30, evaporation 6·3. Observations taken at the Assuan reservoir show the relative importance of average month's temperatures and average month's wind velocities. The results do not, of course, aid in the establishment of a relation between actual wind velocities, actual temperatures, and rates of evaporation, but they are of practical use for purposes of comparison.

Humidity and Evaporation.

By taking a sufficient number of observations of rates of evaporation, it is possible to establish at the same time the relation between evaporation and air temperature and that between evaporation and humidity. Experiments of this kind with water at a constant temperature seem to be lacking, nor have observers, as a rule, noted the actual temperatures of the water. Results are, however, comparable in groups, such as those with small experimental tanks, and those with floating tanks in deep and shallow waters, respectively.

The following table gives the results of observations at Vehar reservoir, near Bombay, latitude 19° (*Conybeare*), and in Nagpur, 21° (*Binnie*). The values seem to be low, but this hardly affects their application in practice, as the engineer would draw the curves and fix his own zero line on the result of monthly or annual evaporations for the locality.

APPROXIMATE MONTHLY EVAPORATIONS IN FEET WITH GIVEN TEMPERATURES AND RELATIVE HUMIDITIES.

Percentage of Saturation.	Mean Temperatures, Fahr.						
	65°	70°	75°	80°	85°	90°	93°
88	0·14	0 17	0·19	0·21	0·24	0·27	0·30
85	0·19	0·22	0·22	0·23	0·27	0·30	0·33
80	0·22	0·27	0·29	0·30	0·32	0·36	0·38
75	0·24	0·29	0·33	0·35	0·37	0·40	0·42
70	0·26	0.30	0·34	0·35	0·38	0·42	0·44
65	0·28	0.31	0·34	0·36	0·40	0·44	0·46
60	0·30	0·35	0·38	0·40	0·42	0·47	0·49
55	0·32	0·37	0·42	0·46	0·50	0·52	0·54
50	0·35	0·40	0·45	0·50	0·55	0·60	0·62
45	0·45	0·50	0·57	0·67	0·71	0·75	0·78
40	0·61	0·66	0·70	0·72	0·77	0·82	0·84

The figures in the following table are taken from results of observations by the Egyptian Public Works Survey Department (*Cay*). It is clear that the rate of evaporation depends considerably upon the mean altitude of the sun, since, for air temperatures which are nearly the same, the rate of evaporation is affected by the latitude and the month. This is shown by the small tables, and the evaporation at latitude 24° in October with air temperature 83° and humidity 41 may be compared with that at latitude 27° in August with nearly the same humidity.

The effect of altitude upon evaporation was tested at four stations on the same mountain in California with the following results :—

Evaporation at Different Altitudes.—4,500 ft., 2·69 ins. ; 7,100 ft., 2·04 ins. ; 10,000 ft., 1·63 in. ; 12,000 ft., 1·61 in.

Annual Evaporation.

At stations selected as representing the chief irrigation districts of California the following were evaporations for a year (*Fortier*). At Berkeley, the cooler coast area with relatively high rainfall, 41 ins. ; at Chico, the bottom of the Sacramento Valley, 53 ins. ; at Pomona, representing Southern California, 66 ins. ; at Tulare, the San Joachin Valley, 68 ins. ; at Calexico, the Imperial Valley, 71 ins.

The evaporation at a number of representative stations is given in the following table, but the methods adopted in measuring evaporation varied considerably. At Croydon, the evaporation from a 5-in. vessel in air was more than 50 per cent. greater than that from the 12-in. vessel floating in water.

Seasonal and Monthly Losses by Evaporation.

It is often necessary to be able to estimate the losses by evaporation during particular seasons, and monthly rates of evaporation, or daily rates in individual months, are frequently recorded. For considerable areas in India the seasonal losses may roughly be reckoned as: In the cold weather 12 ins., in the hot weather 32 ins., during the monsoon 16 ins.; total, 60 ins.

In the following table, some of the rates of evaporation are comparable, but the table has been drawn up chiefly in order to show the relative rates of evaporation in different months at the same station.

Losses by Evaporation and Absorption taken together.

In a great many cases the available data of losses from reservoirs are those for evaporation and absorption, or percolation, taken together. The more nearly the engineer can estimate what proportion of the total loss is due to evaporation alone, the more easily will he be able to decide as to the necessity or expediency of taking measures to reduce percolation. Fairly high losses may be tolerated from reservoirs where a considerable proportion of the percolating water reaches wells from which it can be lifted and used; and this may in some cases be an advantage when the level of the water in the reservoir is very low, or, at least, a mitigation of the disadvantage. Actual losses by percolation can be estimated when the rate of evaporation is obviously very small. Conversely, the proportion lost by evaporation may be estimated when the losses by percolation are known to be small. The losses may be measured as depths on the maximum waterspread, or as actual depths on the mean of the waterspreads at the beginning and end of each short period of observation. Thus, there are often apparent discrepancies between really similar cases, especially when the reservoirs are very shallow in parts, and when, as often happens, the maximum rate of evaporation occurs when the tank is very low.

Losses by percolation are sometimes very large. The losses from four irrigation reservoirs in the United States were as follows, measured in acre-inches or acre-feet referred to the *maximum* waterspread in acres:—(1) one year, 50·4 ins., all attributed to evaporation; (2) maximum of 2 years, 53·8 ins.; (3) maximum of 4 years, 132 ins.; (4) maximum of 2 years, 17·3 ft., ¾ of which was attributed to percolation.

At Red Hills tank, Madras, a total loss of about 7·5 ft. seems to have been indicated by one set of tests, and 8·39 by another series. An allowance of 9 ft. is now made, and is considered to be ample, a fairly liberal estimate being desirable as the water is used for the supply of the city. Tanks in Rajputana were found to lose 9·77 ft. per annum, of which 3·66 ft. was attributed to absorption.

The reservoirs of the Sheffield waterworks are estimated to have lost only about 15 to 15¼ inches by evaporation and absorption, the loss at Rotherham in a neighbouring area being 22 ins.

The following were the results of observations at Red Hills Tank, Madras, the year being roughly divided into seasons which do not, however, begin and end at even approximately the same dates every year.

SEASONAL LOSSES (INCHES PER DAY) BY EVAPORATION AND ABSORPTION, RED HILLS TANK, MADRAS.

EVAPORATION AND ABSORPTION (ALMOST ENTIRELY EVAPORATION) RECKONED ON THE TOP AREAS OF RESERVOIRS NEAR DHARWAR, BOMBAY PRESIDENCY (*Strange*).

Month.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Total.
Evaporation, ins. per day	0·16	0·16	0·16	0·33	0·67	0·67	0·51	0·31	0·16	0·16	0·16	0·17	3·65 ft.

Evaporation from the Soil.

A study of rates of evaporation from the soil is of practical importance as bearing upon estimates of the actual amounts of water required by crops under varying conditions, and the probable losses from the ground when the water is applied some time before cultivation. The importance of the subject is the greater in proportion to the extent to which the cultivation has the character of fruit growing or gardening, as distinct from the growth of large areas of grain crops. In orchards especially, it is possible so to apply the water that the loss by evaporation is considerably reduced. It is often an advantage to keep the water in distinct channels as long as possible.

CALIFORNIAN EXPERIMENTS ON EVAPORATION FROM THE SOIL.

Important series of tests have been carried out during recent years in California, and have been reported by Mr. S. Fortier, Chief of Irrigation Investigations, United States Department of Agriculture.

The experiments were carried out with tanks about 47 ins. deep and 23½ ins. diameter, sunk into the soil and filled nearly to the brim. These tanks were weighed in order to measure losses. The following tabular statement gives the results of experiments made in July and August on the evaporation from soils containing different proportions of water, measured as inches depth over the area of the surface. In the case of the initial free moisture this represented about 4½ to 6 per cent. The amounts of irrigation water added represented, respectively, very light, light, and ordinary irrigation.

WATER CONTENTS IN SOIL AND EVAPORATION (IN INCHES).

Initial moisture	2·8	2·7	2·7	4·1
Irrigation water	0	2·6	4·8	6·3
10 days' evaporation . . .	0·4	0·9	1·2	1·5

Evaporation from the soil may be much reduced by beating or crumbling the dry surface to a powder, by spreading a layer of finely divided soil over the surface, or by irrigating by means of furrows, afterwards spreading the dry soil from between the furrows by some means which will tend to crumble or powder it. In small-scale irrigation and where the cost of the water is high these considerations may be of importance. The following results were obtained in California with experimental tanks containing sandy loam, the evaporation from which when it was left uncovered after the water had been applied was compared with the evaporation after coverings of different depths of finely divided sandy loam had been added. The result of the experiment with the thinnest layer is, of course, the most important generally. During the fourteen days of the experiment the shade temperature of the air at noon was often more than 100°, while the soil temperature in the sun, at noon, varied from 120° to 140°. The figures were :—

Evaporation in hundredths of an inch per day : from uncovered soil, 72·5 ; from soil protected by a 4-inch layer, 20·6 ; 8-inch layer, 10·0 ; 10-inch layer, 2·0.

The following were the results of a twenty-one days' test.

SOIL EVAPORATION IN PERCENTAGE OF WATER APPLIED.

Days	2½	6½	10	14	17	21
Bare soil . . .	11	18	21	25	28	32
3-inch cover . .	2	5	7	9½	11½	14

A further series of experiments was carried out with tanks 47 inches deep and 23½ inches diameter.*

* See *Engineering News*, Sept. 5, 1912, but note that in figs. 2 and 3 the diagrams of evaporation in inches have been accidentally transposed.

In one set of tests the tanks were nearly filled with soil, leaving room for the covering of loose soil in each case, spread after the application of the water, while in another set of tests the tanks were nearly filled and the water applied at the bottoms of furrows of corresponding depths, the soil being afterwards spread. The following table gives the results of both experiments:

EVAPORATION AND SOIL COVERINGS.

Period after water was applied: days		7	14	21	28	21	28
		Evaporation in percentage of water applied.				Evaporation in inches.	
Surface irrigated and left		17·5	25	31·5 (29)		1·75	
Surfaces irrigated and covered with loose soil (inches)	3 ins.	4·8	9·5	13·7 (12·5)		0·75	
	6 ins.	1·5	3·2	6·0 (5·7)		0·34	
	9 ins.	1·5	1·3	4·1 (3·3)		0·22	
Surface irrigated and left		13·2	16·4	18·6	20·8		1·25
Water applied at the bottoms of furrows, depths in inches	3 ins.	9·2	12·0	14·9	16·5		0·99
	6 ins.	7·0	9·6	12·3	14·3		0·86
	9 ins.	6·1	7·5	9·9	12·0		0·72

In the column for the 21st day, the figures in brackets are calculated from the evaporation in inches, and possibly correspond to earlier readings. The other figures in the column are taken from the curve.

Relation between Evaporation from Soil and Evaporation from Water.

The experiments, on the results of which the table below is based, showed what were the evaporations from soils containing different proportions of water, and from a water surface.

Percentage of Free Water.	Temperatures, Fahrenheit.				Weekly Evaporation in Inches.	
	Air in Shade.	Soil in Shade.	Soil in Sun.	Surface of Water.	Soil.	Water.
Saturated.	71°	76°	95°	77°	4·75	1·88
17·5%	76°	78°	106°	80°	1·33	1·94
11·9%	76°	78°	106°	80°	1·13	1·94
8·9%	76°	78°	108°	80°	0·88	1·94
4·8%	76°	78°	108°	80°	0·25	1·94

ANNUAL EVAPORATIONS IN INCHES DURING TWELVE YEARS, LEA BRIDGE, ENGLAND.

Water: max., 26·93; min., 17·33; mean, 22·2.
Soil: max., 25·14; min., 12·07; mean, 19·53.
Sand: max., 9·10; min., 1·42; mean, 4·65.

(*Greaves.*)

Evaporation from Ice.

At Boston waterworks, U.S.A., the evaporation from ice was about 0·06 inch per day, of ins. for the cold season.

Water Losses from Irrigation Canals.

No general rules can be given for estimating the rate at which water is lost from irrigation nals. Some are practically watertight, and only lose water by evaporation, while others lose rge proportions of their supply by leakage.

On the Ganges Canal, at one period the water sent down was accounted for as follows:— rigation, 56 per cent.; loss in canal, 15 per cent.; in distributaries, 7 per cent.; in village water- urses, 22 per cent.

In the Punjab, a loss of 8 cusecs per million square feet of wetted surface has been allowed, d larger amounts in some cases. Certain canals with discharges from 400 to 450 cusecs were

found to lose about one cusec per mile. The Bari Doab Canal, when eighteen years old, lost about 12 to 14 per cent. of its discharge in a length of fifty miles.

Recently, instead of allowing 8 cusecs per million square feet of wetted area, it has been usual to allow, within the limits 4 ft. to 12 ft. depths, one cusec per foot depth per million wetted square feet.

Many canals lose a great deal of water for some time after their construction, and afterwards become reasonably watertight. The deposit of silt at a reasonable rate for some time after the canal is in service may be facilitated by suitable designing of the cross-sections and temporary adjustments of levels at the falls; but no general rules can be given as to this difficult problem.

When L is the loss from a canal, measured in the first mile, the loss up to a further distance of D miles is $L\,D^x$, where x varies from $\frac{5}{6}$ to $\frac{9}{8}$.

Losses through a Dam.

An extreme case of seepage through a gravel fill dam. The dam was 70 ft. high; upstream slope, 3 to 1; downstream slope 1½ to 1. With the gates closed the seepage rates were approximately, during three years: with 20 ft. of water (gauge height), 60 cusecs; with 30 ft. of water, 84 cusecs; with 40 ft. of water 100 to 120 cusecs; with 50 ft. of water, 112 to 135 cusecs.

Capacities of Canals: Mean Velocity.

The discharge or capacity of a canal or river is the product of the cross-sectional area and the mean velocity. The mean velocity is usually found from Kütter's formula (see p. 1481), a coefficient of roughness, n, being chosen with regard to the nature of the soil and the probable behaviour of the canal with respect to silting and erosion. Since the formula takes account of the water slope or fall, and of the hydraulic mean radius,

$$\frac{\text{area}}{\text{wetted perimeter}}$$

every measurement or calculation of discharge by other means tends to fix the value of n for the particular conditions of the bed of the canal or stream. Small discharges may sometimes be measured directly in basins or symmetrical pools, and at notches or specially prepared weirs (pp. 1348-1352), but calculations for discharge over large weirs are themselves subject to disturbing factor and their value in the determination of n is limited.

For irrigation canals in favourable soils and working under favourable conditions the value $n = 0{\cdot}0225$ is considered suitable, and this value has been adopted in the design of very important works. For canals in less favourable conditions the value 0·025 is often adopted, and for canals distinctly below average conditions n may be taken as 0·0275. The value 0·030 may be applied to some rivers and to canals in 'defective condition,' whilst for channels which are much obstructed n may be taken as 0·035. The first two values above are those of most importance in irrigation engineering. For aqueducts of rubble masonry n may be taken about 0·017 to 0·020, and for ashlar and brickwork, 0·013.

Bazin's Formula.

Bazin's new formula is often used for channels, especially for those which, in irrigation systems, are relatively small. It is derived from the general formula

$$V = c\sqrt{RS},$$

by making

$$c = \frac{157{\cdot}6}{1 + \frac{m}{\sqrt{R}}},$$

where c is the coefficient, and V, R, and S have the values given on page 1481.

m = 0·109 for smooth cemented surfaces.
= 0·29 for ashlar and brickwork.
= 0·83 for rubble masonry.
= 1·54 for very smooth earthen channels, pitched, or partly pitched.
= 2·36 for ordinary earthen channels.
= 3·17 for canals encumbered with weeds or boulders.

Direct Measurement of Mean Velocities.

The Use of Floats.—Floats of various kinds have been employed for the measurement of the velocities of canals and rivers, being sent down the reach so as to maintain as far as possible their proper positions in the cross-sections, the average velocity being calculated from float speeds and depths in each strip of the reach. Double floats are often used, the lower and larger float which is a little heavier than water, being held at a determined depth below the surface by a smaller

surface float to which it is attached by a cord. Thus the velocities at different depths and at different distances from the centre-line of the stream can be measured. The essential difficulty in using these floats is that if the lower float has a specific gravity considerably greater than that of the water the surface float must be relatively large, and affect the result appreciably, while if the specific gravity of the lower float be but little greater than that of the water it is liable to be lifted towards the surface by small upward currents.

For the lower floats both cylinders and spheres have been employed; for instance, cylinders 6 ins. in diameter and 12 ins. long, or 6 to 8 ins. in diameter and 9 to 12 ins. long; and spheres 2 ins. and 3 ins. in diameter.

Various forms of surface floats have been used, including very thin discs of considerable area, intended to slip easily along the surface without seriously affecting the speed of the lower float. This form seems to be suitable in calm weather, while a deeper float of smaller surface area may be preferable when there is a breeze. Calm days are best for float observations of any kind, but if a river or canal flows with or against prevailing winds of considerable velocity observations on calm days may be to a small extent misleading.

Rod Floats.—For canals, and for reaches of rivers in which the water varies but little in depth, a good form is the rod float, which may be a tube weighted at the bottom so as to float upright, or a wooden pole similarly weighted. In the Ganges canal experiments both one-inch poles and one-inch tubes were used, the latter proving to be the better. The rods should float with their bottom ends just clear of the bed of the canal.

Current Meters.—Current meters are often used for measuring the velocity of streams and canals, and must be preferred to floats when there is no reach of sufficient regularity and length for the successful use of the latter. With a current meter the velocity at a particular cross-section may be found, and the measurement of that cross-section will then suffice, instead of the number which the irregularity of a reach may render necessary. It is not always easy in practice to keep the current meter at the desired depth, but in some cases it is held there by a rod. In a sluggish stream, the meter may be towed behind a boat, the speed of which is measured. Current meters should be calibrated, and from time to time tested, by towing them at a measured speed in still water, or, failing that, up and down the same reach of the canal or river. The mechanism of the meter can be stopped and started by a brake, on the stop-watch principle, this brake being worked by a cord from the boat. But some meters are fitted with an electrical apparatus, the wires of which form part of the tow line, and record the revolutions visibly in the boat.

The Pitot Tube.—If a tube be partly immersed, vertically, in a current of water, the lower end being suitably bent and remaining open, the water in the tube rises above the surface of the flowing water. The Pitot tube, designed on this principle, gives approximately the relation, $V = \mu \sqrt{2gh}$, where V = the velocity of the current, and h is the height of the water in the tube above the surface of the stream. Instruments which have been employed have given the results $V = 1{\cdot}7 \sqrt{h}$. A much more elaborate instrument on the same principle (*Darcy*) has also been employed, and has given good results in small channels with fairly high velocities.

Perrodil's Hydrodynamometer.—This instrument is a device for measuring the velocity of a current, by the torsion which is produced in a wire by the pressure of the water against a disc mounted on an arm at right angles to the wire. The velocity is found by the equation $V = c \sqrt{a}$, where a is the angle of torsion, and c a coefficient found by experiment, or calculated from the coefficient of torsion of the material of the wire. The instrument is very sensitive and can be used for very slow currents.

Mean Velocity in a Vertical.—The mean velocity of the water in a given vertical in the cross-section of a stream is also the actual velocity at some proportion of the total depth in that vertical. What this proportion is will depend upon the nature of the stream, and will not be the same for all the verticals. For streams of considerable width and not very variable depth at the cross-section, measurements, by means of a current meter, of the velocities at the assumed depth of mean velocity may yield a fair approximation to the mean velocity of the stream, and a closer approximation may be obtained by making preliminary tests, with rod floats for instance, to determine the depth of mean velocity in the particular case. Values given usually lie between 0·60 and 0·75, or 0·60 and 0·70 of the depth.

Relation between Mean and Maximum Velocities.—For a rough estimation of the velocity of a stream the maximum surface velocity may be measured and the mean velocity deduced from it. If V be the maximum velocity, the mean velocity is KV, where K is a coefficient usually ranging from 0·60 to 0·80. In the following table values of K are given for earth channels and rubble masonry channels.

VALUES OF 'K' IN THE EQUATION 'V MEAN = KV MAXIMUM.'

Hydraulic mean depth (feet)	1	2	3	4	5	6	7	10	15	20
Rubble masonry channels	·77	·79	·80	·81	·81	·81	·81	·82	·82	·82
Earthen channels	·65	·71	·73	·75	·76	·77	·78	·78	·79	·80

Critical Velocity.

The 'critical velocity' is that mean velocity at which, for a canal of given depth, the current will neither deposit much silt nor unduly erode its bed. A determination of the critical velocity the theory of which was evolved by R. G. Kennedy (see Min. Proc. Civil Engineers, vol. cxix.) is of great importance in the design of irrigation canals. The removal of silt from the canals is costly, and the loss of valuable fertilising material is a serious matter to the cultivators. A large amount of silting of the canals and distributaries is often inevitable, but attempts are made to lessen it by designing the canals in accordance with the principle of critical velocity.

The equation for determining the critical velocity for a given depth of water in the canal is

$$V_o = cd^m.$$

The values of c and m vary somewhat according to the nature of the silt. For fine sand-silt brought down from the hills usual values are, $c = 0{\cdot}84$ and $m = 0{\cdot}64$. The following table gives the critical velocities calculated on this basis, for different depths, and the observed critical velocities on the Shwebo and Mandalay canals, Burma. With the latter velocities there was on the whole, a slight tendency to scour.

Critical Velocities.

Depths in feet	1	2	3	4	5	6	7	8	9	10	12	15	20
$V = 0{\cdot}84\ d^m$, suitable for the Punjab	0·84	1·30	1·70	2·04	2·35	2·64	2·92	3·18	3·43	3·67	4·12	4·75	5·71
Observed in Shwebo and Mandalay Canals	—	—	1·72	1·98	2·24	2·48	2·75	—	3·09	—	—	—	—

A canal which would be non-silting on a slope of 1 in 7,600 if drawn from the Indus in Sind would require to have a slope of 1 in 4,200 to be non-silting if carrying the silt usually found in the Punjab (*Buckley*).

If the theory of critical velocity be accepted as regards silting and erosion up to the old limit of velocity for different soils, but be rejected when those velocities are reached, the maximum depths allowed for large canals will be correspondingly restricted. If, for instance, a maximum velocity of 3·5 ft. per sec. be prescribed, the depth will be limited to about 9 ft. On the old theory, a higher velocity would cause scour, while on the theory of critical velocity, greater depths with a limit of 3 to 5 ft. per sec. would cause silting. There is, however, no sudden change in the physical conditions, and if the theory of critical velocity holds up to 9 ft. depth it doubtless holds for considerably greater depths; and it has been accepted in the design of very important irrigation systems.

Hydraulic Mean Depth: Mean Velocity: Scour.

(For the same *actual* R (such as 3·28 ft., or 1 metre) the coefficient for metric units is the efficient for British units $\times \frac{100}{181}$, or $\frac{5}{9}$, nearly.)

Duty of Irrigation Water.

The duty of irrigation water, or the area irrigated by a given rate of flow during the season, pends upon the nature of the crop, the initial proportion of moisture in the soil, the rate of aporation, and the rainfall during the irrigation season. It may also depend upon custom and quired rights and is often affected by the degree of care or of carelessness exercised by the ltivators. All figures relating to duty are, therefore, to be accepted with due reserve for pur-ses of estimates. The duty reckoned on the amount passing the headworks is, of course, less an that reckoned on amounts measured out to the cultivators, and the former figures will be fected by the length of the main canal and principal branches, and the rate of loss therefrom. ie duty of irrigation water may be measured in cusecs continuously for the crop; in feet; or acres per million cub. ft. stored.

On the Jamrao Canal system, India, the duty of one cusec per 50 acres has been allowed for ring the inundation season, and 100 acres during the cool season. The duty has been as high 83 acres in the inundation season, for 'dry crops' such as millet and cotton. In the Punjab 0 acres has been allowed for in the rains, and 200 acres in the cool season.

The following duties, in acres per cusec, may be noted:—

Palked canal, Bengal Deccan, 63; Ekrak tank project, Bombay, 123. Pahakarpur canal, mbay, 165; Kabul river canal, Bombay, 114; Lower Swat river canal, Bombay, 175; Letabo ial project, Transvaal, 145; Mooi river, Transvaal 145.

Duties of Certain Important Irrigations.

Lower Chenab: at heads of distributaries, kharif crops, 89 to 111, usually about 95; rabi crops, 217 to 284, usually about 250. At heads of canals: kharif, 73 to 95, usually about 75; rabi, 190 to 237, usually about 220.

Jamrao: kharif, 85; some branches give 90 at their heads, and one gives 100; average at heads of branches, 85.

Sind: proposed under conditions to be brought about by the Sukkur project; kharif crops, 87; rice, 43½; rabi crops about 180.

Kharif Crops: Triple Canal Project, 100; Lower Bari Canal, 109; other cases, 65 to 75, and 85.

Rabi Crops: Lower Bari Canal, 200; Lower Chenab, 208; Upper Bari Doab, 234; Lower Bari Doab, 198.

By amounts: in Kathiawar, jowari, a grain crop, requires 100,000 cub. ft. per acre, and in Jeypore State the same crop requires about 120,000 cub. ft., including losses and contingencies. In the Madras Presidency, where large areas are irrigated from numerous shallow reservoirs, the quantity, including all losses, which is stored per acre is, roughly, about 216,000 cubic ft., or nearly 5 ft. depth, for the 5 months' 'monsoon' rice crop, and 175,000 cubic ft., nearly 4 ft. depth, for a cool weather rice crop. In Central India, the storage is about 200,000 to 250,000 cubic ft. per acre.

Total Depths in Inches.

Punjab: wheat, barley, and poppy, 10·6; senji, 10·5; gram, 3·4; sugar cane, 25·3; Indian corn, 10·6; cotton, 10·6; charki, 6·3.

Punjab: the Colony Canals (H. W. Nicholson); not including preliminary watering of the ground: kharif crops: sugar-cane, 30 to 45; rice, 35 to 40; cotton, 12 to 20; maize, 12 to 18; great millet, 6 to 9; rabi crops: wheat and barley, 9 to 10; sometimes 15 for wheat; toria (*Brassica campestris*), 6 to 10; senji (*Mendicago sativa*) 15 to 20. *Bari Doab:* kharif crops, 32; rabi crops, 20.

Duty of Irrigation Water: Averages or Estimated Averages: Acres per Cusec.

(Duty × 14·3 = hectares per cu. metre per sec., or, $\frac{6{,}040}{\text{duty}}$ = cu. metres per day per hectare.)

Southern California, surface irrigation, 150 to 300; S. California, sub-irrigation, 300 to 500 Southern Arizona, 100 to 150; New Mexico, 60 to 80; Utah, 60 to 120; Colorado, 80 to 120; Northern Italy, 60 to 150; Madras Presidency, rice 66, 'dry crops' 132.

The average duty of five canal irrigation systems in the Bombay Deccan, from 1894–1895 to 1900–1901, excluding two famine years, was, successively:

For *Kharif*, 70, 52, 74, 111, and 138, with a mean of 89; and for *rabi*, 60, 68, 90, 75, 85, with a mean of 76.

Costs of Irrigation Projects.

The costs of irrigation projects in India do not admit of comparison unless the nature and purpose of the project in each case be described in considerable detail. Some projects are highly productive, others are protective, and many are of an intermediate character. The conditions are very different in the United States, and, on the assumption that the works have been carried out on the narrower economic basis, the following costs may be worth noting.

Costs of Irrigation Projects of the United States Reclamation Service.

Area in Thousands of Acres	216	206	164	131	129	118	103	100	72	60
Cost of water rights in dollars per acre	30 to 36	22 to 30	45 to 50	55 to 66	45 to 55	22 to 30	52	30 to 35	30	45

Cost of Irrigation with Pumped Water, S. Africa.

On the total cost of 63 pumping projects, the cost per acre was 6*l.* 17*s.* Near the coast, the cost of putting two feet per acre on to the land may be taken as between 1*l.* and 2*l.* for a 50-ft lift, and between 1*l.* 10*s.* and 2*l.* 10*s.* for a 150-ft. lift. Up country, the costs would be about 2*l.* 10*s.* and 3*l.* respectively. (*Legg.*)

COSTS OF IRRIGATION: NEBRASKA.

In Nebraska, 1920, 1 per cent. of farm lands irrigated; average per farm, 147 acres; capital invested, 5*l.* 4*s.* per acre; annual cost of operation and maintenance, 6*s.* 3*d.* per acre; average depth of irrigation water on the land, 2·4 ft.

Waste Weir Capacities.

For rates of rainfall and calculations for run-off, see 'Rainfall,' pp. 1461, 1462. For discharges of weirs, see pp. 1348–1352. The following formula is used in India for the discharges of the overflow weirs of storage tanks and reservoirs.

Discharge of clear overfall weirs :—

$$D = c\,b\,\sqrt{H^3}.$$

D = discharge in cusecs; b = width of the crest in feet; H = total height above the weir crest in feet, allowing for afflux; c is a coefficient usually about 3·333, or as low as 3·25.

In ordinary practice in the Bombay Presidency, India, it is usual to assume a general rainfall over the whole of a small catchment, and to calculate the run-off accordingly, thus :—

Catchment in Sq. Miles . . .	Up to 5.	5 to 10.	10 to 25.	25 to 75.	75 to 150.	Over 150.
Run-off in ins. of rain per hour .	2·00	1·50	1·25	1·00	0·75	0·50

In using this table special circumstances have to be considered; mountain catchments would be given larger runs-off, and for catchments wholly in the plains smaller runs-off would be assigned. (*Strange.*)

METRIC VALUES OF c IN $V = c\sqrt{RS}$. $n = 0{\cdot}0250$.

Basic Economy of Dams.

Volume of Water stored per Unit Volume of Masonry in the Dam.

Poona, India, 62; Beetaloo, Australia, 79; Booton, New Jersey, 200; Cross River, New York, 610; Granite Springs, Wyoming, 716; Wachusett, Massachusetts, 1,369; Sodom, New York, 1,569; Sweetwater, California, 1,679; Assouan, Egypt, 1,980; Periar, Madras, 2,620; Roosevelt, Arizona, 7,426.

Losses of Irrigated Area by Degradation.

The principal causes of losses of irrigated area, or of reduced productivity, are alkalinity of the soil and waterlogging. As regards the latter, the importance of including measures for effective drainage, as far as may be necessary, in the irrigation project, is now generally realised. The measures to be taken in order to deal with alkalinity cannot be briefly described in general terms, but are fully discussed in standard works. The extent of the two evils, taken together, in the United States may be judged from the following quotation: 'It is safe to say that 15 to 20 per cent. of the lands reclaimed by irrigation have been ruined or are endangered by seepage or alkali. Assuming that a total of 20 million acres have been irrigated within the United States, then from 3 million to 4 million acres have been affected, and possibly a million acres rendered useless." (D. W. Murphy, 1923.)

Silting of Reservoirs.

Muchkundi: capacity, 704 million cub. ft.; catchment, 26 sq. miles; accumulated silt, in 22 years, 58 million, and in 26 years, 64 million cub. ft.; respective rates, 101,000 and 95,000 cub. ft. per sq. mile of catchment per annum. Capacity reduced 8·2 per cent in 22 years; 9·9 per cent. in 26 years.

Gokak: capacity, 908 million cub. ft.; catchment, 1080 sq. miles; accumulated silt, in 18 years, 155 million, in 19 years 174 million, and in 20 years, 189 million, or 8,750 cub. ft. per sq. mile of catchment per annum. Capacity reduced 28 per cent. in 20 years.

Lake Fife: not having sluices for silt, in the dam; at 14 ft. above sill, area of water surface: in 1883, 88·76 million sq. ft.; in 1905, 72·34 million sq. ft.; loss of capacity in 22 years, 16·33 million cub. ft., or 18 per cent.

Lake Whiteing: having sluices for silt, in the dam; no appreciable change in capacity in 5 years.

Proportions of Silt Borne by Rivers and Canals.

Reputed maximum proportions of silt to water, by weight: Rivers—Mississippi, 1/572; Nile, in August, 1/666; Indus, at Sukkur, 1/163 to 1/198, velocity 6·4 to 8·3 ft. per second; a tidal river in East Bengal, during six days, ranged from 1/455 to 1/25. The Vaal, rising, and 3 ft. 6 ins. over weir, 1/268; falling, and 1 ft. 7 ins. over weir, 1/660; Rhône, velocity 8 ft. per second 1/45; Vistula, velocity 10 ft. per second, 1/48; Kistna, June, 1/42.

Cubic feet of damp silt per million cub. ft. of water: Sirhind canal (1897, 32,600 million cub. ft. intake), 5,464, (1895, 43,000 million cub. ft. intake) 1,650, (1896, 54,600 cub. ft. intake) 2,343. Sone canals, June, 1,875; July, 3,250; Aug., 2,750; Sept., 625; Oct., 62. Guadalquivir, on successive dates, March 30 to May 2, 2,321, 775, 521, 695, 2,048, 596, 273, 222, 198.

Fluctuations of the Vaal River.

(W. Van. Warmelo.)

A table gives for eight gauging stations on the River Vaal and its tributaries the average flow for each month of the year, in one case based on 2 years' observations, in two cases 8 years', in other cases 9 to 17 years'. A rough averaging of the 8 cases gives the following months' flows, as percentages of the average 12 months' flow: Oct., 4; Nov., 10; Dec., 12; Jan., 17; Feb., 21; March, 20; April, 7; May, 2; June, 1¼; July 1½; Aug., 1½; Sep., 3. For the River Vaal, at Standerton, the figures, based on 16 years' observations, were: Oct., 5·56; Nov., 14·99; Dec., 14·75; Jan., 27·15; Feb., 20·12; March, 11·49; April, 2·39; May, 1·05; June, 0·63; July, 0·53; Aug., 0·72; Sept., 0·62.

A Typical South African Irrigation.

Van Rynveld's Pass: catchment, 1,477 sq. miles; average rainfall, 14½ ins.; area irrigated, max., 22,314 ac.; average, 17,000 ac. Dam, length, 1,170 ft.; crest width, 10 ft.; clear height (max.), 109 ft.; height plus deepest foundation, 152 ft.; capacity of reservoir, 64,000 acre-feet.

The Hartebeestpoort River: irrigation controlled by the Hartebeestpoort Dam; altitude of river bed, 3,827 ft.; catchment, 1,560 sq. miles; average rainfall near the dam, about 23 ins. Dam: height above river bed, nearly 190 ft.; thickness at base, 73 ft.; radii at base, downstream face, 75 ft., upstream face, 148 ft.; increasing radii to vertical top section where the upstream face radius is 240 ft.; one tangential abutment; crest and top section width, 15 ft.; both batters 1 in 5·714; freeboard above full supply level, about 22·75 ft., capacity of reservoir, at waste weir crest level, 136,241 acre-feet; capacity above outlet level, 123,200 acre-feet; waterspread at F.S.L. (waste weir crest level), 6·7 sq. miles; 9·2 sq. miles available.

The Sukkur Barrage Project (Under Construction).

Barrage 4,926 ft. long, with 66 openings of 60 ft.; gates, 63 ft. 3 ins. by 18 ft. 6 ins. in height; The Rice Canal, capacity, 12,346 cusecs; length, 87 miles; North-West Perennial Canal, 4,313 cusecs, 97 miles; South-East Perennial Canal, 2,767 cusecs, 140 miles; Rohri Perennial Canal, 10,256 cusecs, 205 miles; Eastern Nara Supply Channel, 12,200 cusecs, 15 miles; 242 miles of River Nara canalised. Totals of areas to be irrigated, acres: rice, 823,000; cotton, jowari, etc, 1,739,000; rabi crops, 3,338,000. Cultivation acreage, total, 5,900,000 annually in a total commanded area of 8,132,000 acres. Estimated cost, 1,836 lakhs; or, taking the rupee at *1s. 4d.*, 12,240,000*l.*; taking the rupee at *1s. 6d.*, 13,770,000*l.* Estimated annual tonnages of crops after 30 years' development: rice, 515,000: cotton, 190,000; jowari, &c., 575,000; wheat, 935,000.

Dimensions of Sluices.

Lake Menty Dam, Sundays River, South Africa.—Five free roller sluice gates, each 30 ft. wide by 25 ft. high; about 25½ tons weight; counterpoise, 53 tons; designed for water head of 26 ft. Each gate is built up of latticed bowstring girders as the span elements.

Sennar Dam, Blue Nile.—The portion called the 'sluice dam' is 606 m. (1,988 ft.) long, with 80 sluices 2·0 m. wide by 8·40 m. high to the springers (6·56 ft. × 27·55 ft.). The head regulator has 14 sluices, each 3·0 m. wide by 5·0 m. high to the springers (9·84 ft. × 16·4 ft.); seven to be provided with gates and seven (held in reserve) blocked.

Automatic Syphon Spillways: Early and Recent Examples.

Champlain Canal, U.S.A. (G. F. Stickney, 1910).—At lock No. 9 the syphon spillway was 57 ft. long as against 200 ft. if an ordinary weir had been built for the small permissible depth on sill. Each syphon had an area of 7¾ sq. ft.; head, 10½ ft.; discharge, 160 cusecs; flared inlets. At Whitehall, on the same canal, a similar weir, 6 syphons; 16 ft. head. These syphons were formed in the body of the weir. (See *Engineering News*, October 13, 1910.)

Maramsilli Reservoir.—A syphon spillway to pass 40,000 cusecs. (See Paper No. 4602, *Proceedings Inst. C.E.*, by Powys Davies.)

Bridgeport Dam, Nevada, 1926.—Cross-section, 3 ft. by 6 ft.; air vents in syphon hoods at different elevations, so that the syphons will come into action one at a time.

Arch Dam: Measured Strains under Water Load.

Stevenson's Creek Dam, California.—A concrete dam built for the purpose of measuring strains under water load and comparing deduced stresses with calculated stresses. Founded on solid rock, in a gorge. Height 60 ft., crest length 140 ft., upstream radius 100 ft., thickness at base 7½ ft., at crest 2 ft. Tests were made at night to minimise temperature effects. At 30 ft. below crest the maximum deflection under full load, 60 ft. water depth, was 0·378 in. At the crest the deflection was downstream at the crown and upstream between the quarter points and the ends. Computed for a modulus of elasticity of 3,600,000, the stresses were: at the crown, 260 lbs. per sq. in. (theoretical 207); at the abutments, 900 to 1,000 lbs. per sq. in. (theoretical 879). Considered as assigned in part to arch resistance and in part to vertical elements resistance, the share of the latter in sustaining the water load seems to have been less than that assigned by theory. This may have been due to the formation of a horizontal crack at the base of the upstream face between the dam and its foundation, which appeared when the water had risen to 30 ft. depth. The formation of this crack is in accordance with the theory regarding the design of the foundations at and near the upstream toe of a dam, according to which the dam should not there be keyed into its foundation. [See 'Mass Dams and Dams of Arches' (R. Ryves): Madras Government Paper, 1910.]

Measured Shrinkage of an Hydraulic Fill Dam.

(*C. H. Eiffert*, '*Engineering News Record*,' *Jan.* 27, 1927.)

Huffman Dam.—Height of dam above ground level, about 62 ft.; width of crest, 32 ft.; symmetrical to central vertical plane; two berms; both slopes, from toe, 3 to 1; between berms, 2½ to 1; to crest, 1·825 to 1. Shrinkages, including settlement of foundation which is believed to have been very small: at 40 ft. below crest level, 0·40 to 0·68 per cent.; at 30 ft. below crest level, 0·31 to 0·54 per cent.; at 20 ft. below crest level, 0·44 to 0·64; at 10 ft. below crest level, 0·24 on east side and 0·73 on west side; at the crest, 0·60 on the east side and 0·49 on the west side; average, 0·51 per cent.

SECTION XXVI

PART III

RAINFALL — WELLS — WATERWORKS — DAMS — FLOW OF WATER IN PIPES—WATER PIPES—WATER TANKS.

RAINFALL.

(Contributed by Reginald Ryves, A.M.Inst.C.E., M.Cons.E.).

Rainfall in the British Isles.

For valuable data and studies relating to rainfall in the British Isles reference may be made to a paper on 'The Distribution of Mean and Extreme Annual Rainfall over the British Isles,' by H. R. Mill (Min. Proceedings Civil Engineers, vol. clv., 1903–1904); also to 'Variations in the English Climate during the Thirty Years 1881–1910,' by W. Marriott (Quarterly Journal R. Met. Soc., July 1911). The former paper is accompanied by useful maps of rainfall distribution, and the latter by diagrams showing deviations from the mean values, month by month, for temperature, rainfall, number of 'rain-days,' and atmospheric pressure. Temperature and the number of rain-days have a considerable bearing upon water-supply and sewerage schemes. Reference may also be made to a paper on 'The Abnormal Summer of 1911,' by C. Harding (Quart. Journal R. Met. Soc., January 1912).

The rainfall of each of the three divisions of the British Isles decreases from 100, 80, or 60 inches in the mountains and moorlands near the Western coasts to about 25 inches (over a few areas down to 20 inches) near the Eastern coasts of Scotland and England, and in the Midlands, and to about 35 inches on the East coast of Ireland. Over more than a third of England the rainfall ranges from 25 to 30 inches, and over a considerable total of smaller areas the fall is from 30 to 40 inches. There is a similar range, 30 to 40 inches, over about half Scotland, and a large area in the Western Highlands has a rainfall ranging from 60 to 100 inches. Over the Eastern half of Ireland the fall is from 35 to 40 inches, and over most of the Western half from 40 to 50 inches. For the period 1870–1899 the average annual falls were as follows: England, 31·62; Wales, 49·53; Scotland, 46·85; Ireland, 42·28; British Isles, 39·25. For the period 1881–1910 the average for England was 31·90.

Average, Maximum and Minimum Rainfalls.

It is generally agreed that a period of 30 to 35 years (*Binnie*) is long enough to establish for the average annual rainfall a value which will be nearly the true average, if such there be, and anyhow will be the mean of probabilities. For reasons, some of which are theoretical and others practical, many engineers prefer a period of 35 or 30 years to the longer periods for which records are in some cases available.

In the British Isles for the period 1870–1899 the rainfall of the 'wettest' year exceeded the average fall by 43 per cent., and that for the 'driest' year was 29 per cent. below the average (*Mill*). The following, expressed in percentages of the averages, are the figures for the different parts of the British Isles and for the whole area, taking in every case the wettest and driest years for the area referred to, period 1870–1899:—

England, 146 and 70; Wales, 147 and 75; Scotland, 147 and 72; Ireland, 133 and 69; British Isles, 143 and 70.

For the period 1881–1910 (*Marriott*) the percentage figures for England are 131 and 76·7. This period seems, however, to have been somewhat abnormal. The actual rainfalls compare thus:

England.	Maximum.	Average.	Minimum.
Period 1870–1899	46·98	31·62	22·83
Period 1881–1899	41·78	31·90	24·45

This suggests that although the 30 years' period may be satisfactory as regards the average annual rainfall it may not include a fall approximating to the maximum, nor one approximating

to the minimum. Probability would, indeed, seem to be against such a result, but it is interesting to note the differences of nearly 5 inches and 1½ inch above.

At stations in the British Isles the following annual rainfalls in percentages of the average have been recorded : 58·8, 59·8, 61, 60·5, 63·6 and 64·5, showing defects from 35½ to 41 per cent. of the averages.

Sir Alexander Binnie considered the true mean rainfall to lie between the period of 33 and 35 years. From 14 stations scattered over the world he arrived at the following results :—

1. The percentage of years, in which the rainfall is above the mean rainfall, is 45·8.
2. The percentage of years, in which the rainfall is below the mean rainfall, is 54·2.
3. The average fall of wet years is 1·19 of the mean rainfall.
4. The average fall of dry years is 0·83 of the mean rainfall.
5. The average fall of the three consecutive dry years is 0·76 of the mean rainfall.
6. The maximum rainfall is 1·52 of the mean.
7. The minimum rainfall is 0·59 of the mean.
8. The proportional number of periods of three consecutive dry years in 100 years is 20·3.

Rainfall in Foreign Countries.

The following figures are maximum annual rainfalls (for whole countries) expressed as a percentage of the average annual fall in each case (*Binnie*) :

Norway, Denmark, Holland and Belgium, 148 per cent. ; France. 161 ; Italy, 159 ; Switzerland, 147 ; Germany, 139 ; Bavaria and Austria, 144 ; Russia, 166 ; India, 162 ; Australia, 156 ; North America and Canada, 141 ; typical observations for the world, 151.

The following are actual inches of annual rainfall, maximum, average and minimum, for a period of 24 years, in the Madras Presidency, 7 stations :—

70, 47, 31—78, 40, 17—48, 29, 9—60, 50, 17—43, 28, 17—165, 117, 87—182, 131, 95.

The probable figures for a given area, when they cannot be based on records fairly covering the area itself, may be estimated partly from station records and partly from averages for a larger area, the probable range of maximum and minimum values being studied from both points of view, and depending to a considerable extent upon the size of the area under consideration.

The Driest Group of Three Years Running.

Experience has shown that the most serious shortage in water-supplies usually occurs as the result of the defect of rainfall in the driest group of three years running, and this consideration is usually one of the factors in the design of water supplies and irrigation works. It must not be assumed, however, that there are no cases in which the worst single dry year is not the governing factor, and on the other hand, the worst period may in some countries be more than three years. The principle is, however, to be accepted in all cases, inasmuch as there is, for every place, some period which is that towards the end of which the effects of a drought will probably be most severely felt. The rainfall records will go far towards disclosing the critical period, but the nature of the soil, and the extent and nature of natural storage facilities, may also have to be taken into consideration.

The estimated average annual rainfall for the three years' period is sometimes put at 80 per cent. of the general average, though it is doubtful whether so high a percentage could be relied upon in any country. Sometimes it is put at 75 per cent. At Cape Town the average rainfall for the driest three years is 73 per cent. of the general average. In any case it must be remembered that the available run-off in the three years, as will be shown later, may be a much smaller percentage of the average available run-off. If, out of 50 inches of rain, 15 are lost by evaporation and absorption, we have 35 inches available. With a 40 inch, or 80 per cent. fall, we should have 25 inches available, or about 71 per cent., and the loss in the dry year might be greater than the average.

Run-off and Losses.

The available supply and the losses by evaporation and absorption are often expressed as percentages of the rainfall, but the amount of run-off or of loss bears no definite relation to the amount received by the catchment. The yield of a catchment area may better be reckoned as proportionate to the rainfall less some constant quantity which may be called the 'handicap' (*Lapworth*). This method is not, however, applicable to all cases, though in most cases it is suitable for the purposes of preliminary plans and may often give quite accurate results. The following are 'handicaps' for different areas (*Lapworth*) :

Average in Great Britain, 10 to 12 inches ; Thames Valley, 16 inches ; parts of Dartmoor, nearly 18 inches ; North-Eastern and Eastern parts of the United States, about 16 to 20 inches ;

in California, 23 inches or more; in India, up to 30 inches; in South Africa, about 25 inches. The mean annual loss from 29 streams in England ranged from 28 inches (loss) to a *gain* of 2 inches. Average about 14 inches; range of 18 of the 29, 11 inches to 17 inches. Small losses, or, in extreme cases, gains, may be the result of precipitation not recorded by rain gauges. In some catchments the dews are very heavy; in some there is often heavy condensation on trees and herbage, especially heather, during fogs or drifting mists.

It is necessary to find the particular 'handicap' in every case, since its amount necessarily depends upon topographical and geological features, upon the area of the catchment and the manner in which the water is collected. Further, it must be noted that the method is by no means generally applicable, and notably fails when the effect of one year upon the next is strongly marked. In the Ajamenta Valley, Gold Coast Colony, the following, in inches, were year's falls and the corresponding yields (*Hunter*):—

38·8, 1·800—59·9, 8·280—47·7, 2·540—42·4, 0·140—30·8, 0·560—29·6, 0·004—40·2, 0·006.

Again, if we take the figures for the Sweetwater catchment basin, California, we find that the following comparisons may be made (*Folwell*):—

A year's rainfall of 21 inches yielded 12 per cent., but a fall of 23·4 inches yielded only 9 per cent., while another year's fall of over 23 inches yielded less than 0·4 per cent. A fall of 17·2 inches yielded 4 per cent., but falls of 18 to 19 inches yielded less than a quarter per cent. The average fall of nearly 21 inches yielded less than 6 per cent., but an actual year's fall of 20 inches yielded 8 per cent.

The yield from the Coolgardie catchment, in a period of six years (*Palmer*) ranged from 0·20 per cent. to 3·5 per cent., while the rainfall ranged only from 19 to 33¼ inches.

In a period of 10 years the worst discharge of the Guadalquivir (Spain) was 9 per cent. of the rainfall, and in the best year it was 50 per cent. In the Karroo, S. Africa, a yield of 2 or 3 per cent. would be expected from a year's fall of 8 to 10 inches, and from a fall of 20 inches the yield would be about 8 or 10 per cent. (*Legg*).

Generally, in dry countries with a small rainfall the ratio of evaporation to the rainfall, or to a part of the rainfall, increases rapidly with a decrease in the actual amount of the fall. Conversely, in wet countries with a fairly large proportion of rainy or cloudy days the effect of relatively dry conditions or of scanty rainfall is not felt to nearly the same extent. In some cases it is found that the rainfall to be considered is that of only a part of the year, and it is then necessary to study maximum and minimum rainfalls, and the worst three years, as applying only to this season. In Natal about ⅞ of the rainfall occurs in the wet season, September to April. In Southern Rhodesia, about ½½ from November to March. In other cases, especially when the area does not feel the full effects of any of the seasonal rains, it is necessary to examine the rainfall records in detail for the worst three years, and to eliminate all falls of less than some predetermined amount (single falls or day's rain). Next, the yield from each of a series of falls should be estimated as, in each case, a proportion depending partly upon the amount of the fall and partly upon the interval which had elapsed since the previous fall. The maximum percentage yield will be assigned to continuous rain on soaked ground and soaked subsoil. In dry areas it may be necessary to adopt such a method of estimating the yield, when, owing to the nature and distribution of the rains, no general rule can be applied to the whole rainfall of the year, or to that of a season. For a rough estimate it may be sufficient to eliminate small or isolated falls and to calculate the yield of the remainder as a diminishing proportion of the remaining rainfall, less some constant. In some conditions the proportion need not be a diminishing one.

Hartebeestpoort Dam (near): altitude over 3,800 ft.—Monthly rainfalls and evaporations (approximate), inches: January, rainfall 4·99 and evaporation 6·51; and in that order, February, 4·11 and 5·65; March 3·31 and 5·07; April 0·80 and 5·13; May 0·69 and 5·10; June 0·06 and 4·35; July 0·27 and 4·91; August 0·73 and 6·60; September 0·48 and 7·91; October 2·26 and 8·41; November 4·66 and 7·63; December 3·98 and 7·40; the year 26·34 and 74·67.

Absorption and Evaporation.

While it is possible, by the exercise of judgment, to form some idea as to the extent of losses by absorption for a particular area, it is clear that the large number of factors involved makes it impossible to lay down any general rules. Under some circumstances all the rain runs off, under other circumstances it is all absorbed, and there is every conceivable intermediate condition.

A few points are, however, worth noting. Clay soils, after the surface is wet, absorb water only very slowly. Some light soils are absorbent up to a given rate of absorption and rainfall in excess of that rate runs off. If the water absorbed by the soil percolates to places where it is available for use, the loss by evaporation from the soil will largely depend upon the average depth of the subsoil water. A dusty surface to a great extent prevents evaporation from the soil.

In practice, the loss from evaporation and percolation taken together is found by gaugings of the streams from the catchment, or, provisionally, is based upon data obtained from similar

catchments, with such modifications as seem to be desirable owing to differences in the conditions. The estimate of the loss by evaporation and absorption, obtained from one set of data, should agree with the estimate of total yield based upon another set of data, or upon general considerations. References to evaporation from free water surfaces and from soils will be found under 'Irrigation,' pp. 1445, etc.

Dr. Walter Leather gives the following formula for estimating evaporation from water surfaces:—

$$E = 2{\cdot}0\ (\log t - 1{\cdot}74) + 0{\cdot}33\ (\log D - 1{\cdot}00) + 0{\cdot}36\ (\log W - 0{\cdot}125)$$

where,

E = Evaporation in millimetres for 24 hours ; D = Dryness = 100 − (humidity at 8 A.M.); W = Mean wind velocity for the 24 hours in miles per hour; t = Mean temperature in degrees F. for the 24 hours.

Rainfall Quantities and Rates.

One inch of rain is equal to :—

2,323,200 cubic feet per square mile; 14,485,000 gallons per square mile ;
3,630 cubic feet per acre; 22,633 gallons per acre.

One inch of rain per hour is at the rate of :—

645 cubic feet per second on a square mile, nearly 1 (1·01) cubic foot per second on an acre:
241,419 gallons per minute on a square mile;
377 gallons per minute on an acre.

Cubic feet per minute = $A_2 r \times 1613{\cdot}7$.

Flood Discharges.

For every area, however small or however large, there is some period of time at the end of which the effect of continuous rain reaches the maximum. What this period is depends upon all the circumstances, the size of the area in question, the nature of the rainfall, the physical character of the catchment, and the nature of the vegetation or of artificial works all affect the result.

The maximum rate of rainfall for the period in question is therefore a leading factor in the calculation of the flood discharge of the area. For some small areas the maximum discharge may be that which occurs when natural storage on the catchment has reached the maximum, and the rate of run-off is then equal to the rate of rainfall, or to some proportion of it, allowing for underground escape of a part of the water. In most cases, however, the maximum capacity of the catchment for surface water is reached only for short periods after the heaviest rushes of rain, and the amount of such storage affecting the result is the average over a relatively long period, and cannot be estimated with any degree of accuracy. A period longer than the critical period will give a lower rate of discharge because the rate of rainfall will be less, and a period shorter than the critical period will give a discharge lower than the maximum because the water from the more distant parts of the catchment will not have time to reach the outlet. If we knew the rate of flow over the ground and along the watercourses we could find the time required for water to arrive at the outlet from the part of the area most distant in time, in many cases the farthest point in distance. But we seldom know these average speeds, except sometimes in the case of a sewerage system. It is usually necessary to have recourse to empirical formulæ, or formulæ partly empirical and partly rational, and the engineer has to exercise judgment in choosing one coefficient affecting the whole quantity or several coefficients affecting different factors. In some large river basins the effects of short storms over several tributary valleys may, by the simultaneous arrival of the resulting floods, yield a larger discharge than that due to the lower rate of rainfall for the critical period corresponding to the whole area. In such cases the purely empirical formula may be better than the rational formula, because the engineer makes a note of every real coefficient established by experience, and all these coefficients are strictly comparable.

Further, in the case of a steep, rocky valley, the river of which drains flat uplands, or glens under dense jungle, the heavier rainfall for the shorter 'period of total contribution' for the main valley may give a larger flood discharge than the smaller rainfall for the longer period of total contribution for the whole catchment. Even in normal river basins, areas projecting beyond the average distance of the watershed of the distant parts of the catchment may be eliminated, the loss in area being more than made up for by the gain in rate of rainfall for the reduced period of total contribution (*Ryves*).

The following formulæ are used in calculating flood discharges of rivers and, in some cases, are also employed for quite small catchments.

Ryves' formula—

$$Q = CM^{\frac{3}{4}}.$$

Q = discharge in cu. ft. per sec.; M = area in square miles, C is a coefficient usually ranging from 450 to 1,000, according to the nature and situation of the catchment; rainfall data are also taken into consideration, by comparisons with established results.

This formula is largely used in Southern India. (Discharge in cu. metres per sec. = the same coefficient $\times \frac{15}{1000} \times$ (area in sq. kilomes.) $^{\frac{2}{3}}$).

Dickens' formula—

$$Q = 825\ M^{\frac{3}{4}}.$$

This is the form in which the equation is usually presented, but it is doubtless advisable to vary the coefficient as in the case of the Ryves' formula.

The Dickens' formula is probably more particularly suited to the conditions of Bengal and other parts of Northern India, but both formulæ may be usefully employed in other countries.

The formula $Q = CM^{\frac{4}{5}}$ has been found to apply, for *ordinary floods* in the New England and Appalachian catchments, with a coefficient C = 130 to 200; in Eastern Middle State river basins, with a coefficient from 60 to 100; and for Western tributaries of the Mississippi, with coefficients from 12 to 50 (*Fanning*).

Chamier's formula—

$$Q = 640 \times R \times C \times \frac{M^{\frac{3}{4}}}{M}.$$

R = average rate of greatest rainfall in inches per hour for such duration as will allow of the flood-water flowing to the outlet from the farthest extremity of the catchment. C = coefficient of surface discharge, giving the proportion of rainfall that may be expected to flow off the surface, M = area of catchment in square miles.

This formula seems to have given good results, and by comparing the calculated discharges for many catchments with those actually observed it should be possible to arrive at some idea of the figures for the rates of flow, from watershed to outlet, upon which the period of total contribution depends and from which, therefore, the rate of rainfall is derived. Since this factor cannot, in comparison of results, be disentangled from the factor C, it will take longer to extend the use of the formula than it does in those cases in which the exercise of judgment and the results of practice focus on to a single coefficient.

In order that the length of the catchment might be taken into consideration the following formula was proposed:

Burge's formula—

$$Q = C \cdot \frac{M}{(L)^{\frac{1}{3}}},$$

where L is the length of the main river or stream in miles; C is usually taken as 1,300.

A modification of this formula has been proposed, as follows (*Jackson*):—

$$Q = C \times \frac{B}{L} 100\ M^{\frac{2}{3}},$$

where L is the extreme length and B the extreme breadth of the catchment area.

It may be suggested that when it is possible to make a fair estimate of the period of tota l contribution, and, therefore, of the maximum rate of rainfall, such an estimate should form the basis of the calculation for maximum flood discharge, and when no such estimate can be made an empirical formula with a single coefficient should be used.

Storm-water Discharge of Sewers.

The same principles that govern the discharges of large river basins hold in the case of the storm-water discharge of sewers, but it is usually much easier to estimate the average rate of flow from the most distant parts of the catchment (measured in time) and, therefore, to estimate the period of total contribution, the rainfall for which can be found from local records.

The following are formulæ employed:

Bürkli-Ziegler's formula—

$$Q = R \times C \times \sqrt[4]{\frac{S}{A}}.$$

Q = discharge in cubic feet per second per acre.
R = average rainfall in cubic feet per second per acre 'during heaviest rainfall.'
C = 0·75 for paved streets; 0·31 for rural districts; average 0·625.
A = area of district drained in acres.
S = general fall of area per thousand.

It is clear that R will depend upon the period of total contribution which will have to be found in each case in order that the formula may be applied. The factor C would, as regards unpaved areas at any rate, also depend upon the period of total contribution.

Kuichling's formula—

$$Q = A \times a \times t \times (b - c \times t).$$

A = area drained, in acres; a, b, c, empirical constants which vary for different localities; t = time required for the concentration of storm water at the outlet.

This formula seems needlessly complicated, since if t be known the rainfall can be found and a single modifying coefficient could be applied to it, as well as one to be applied to the quantity as a whole, if considered necessary.

Lloyd-Davis' formula—

$$Q = \left(60{\cdot}5 \times \frac{60}{Tc} \times R\right) \times Ap.$$

Q = cubic feet per minute; Tc = time of concentration in minutes (time of flow through the longest sewers); R = rainfall in inches during Tc; Ap = percentage of impermeable area in acres.

In some respects this is a good formula, but the permeable area would also affect the total in most cases. It would seem better to treat permeable and impermeable areas separately, and add the resulting discharges together to get the total discharge, but it would be difficult to do this except where the period of total contribution was the same for both parts of the area.

Having found the period of total contribution, the maximum rate of rainfall for that period must be found from local rainfall records. Thus, a curve drawn for records of heavy falls for a district in Southern India gave the following results (*Ryves*):—

Heaviest fall in 30 mins., 2·0 ins.; in 60 mins., 3·0 ins.; in 85 mins., 3·8 ins.; in 104 mins., 4·2 ins.; in 134 mins., 4·8 ins.; in 150 mins., 4·9 ins. Such curves are not necessarily drawn for the heaviest 'spot' falls, which are usually due to cyclones traversing a very narrow path. The maximum spot rainfall may be much greater than the maximum for the storm-water area of

a large town. Even when the maximum rainfall does affect the whole area it is not always worth while to design the works for this fall. For instance, in some places cyclones are rare, and the maximum falls may greatly exceed the largest intervening falls, for periods of many years, being perhaps 4 or 5 times greater. The same principle may hold with respect to large areas, and the cost of works to deal with another fall such as that which occurred in East Anglia in August 1912 or with floods such as those experienced in Paris in 1913, may be so great that it is better to risk the chance of a similar visitation.

Heavy Single Falls of Rain over Considerable Areas in the British Isles.

London, whole area, 2·5 ins. in 24 hours.
Lake District, 714 sq. miles, 5·63 ins.
Eastern Ireland, 1,160 sq. miles, 4·76 ins. } single fall in less than 3 days.

Aug. 1912. East Anglia 18 sq. miles, over 8 ins. in about 24 hours.
" " 238 " 7 " " 24 "
" " 705 " 6 " " 24 "
" " 1,039 " 5 " " 24 "
" " 3,463 " 3 " " 24 "

Before 1912 the maximum fall for 24 hours recorded in Norfolk was 4·48 ins.

Heavy Station Rainfalls in the British Isles.

Inches in 24 hours: Seathwaite, 8·03 and 7·00; Ben Nevis, 7·74 and 7·29; Rosthwaite, 6·94; Angerton Hall, 6·70; Lyme Regis (' in the night,' July), 3·58 ins.; Ballycumber, 3·8 ins. For shorter periods:—Norwich, 0·52 ins. in about 5 min.; Dover, 0·44 ins. in 12 min.; Margate, 0·51 ins. in 20 min.; Hellingley, Sussex, 1·21 ins. in 50 min., and 0·73 ins. in 12 min.; Oxted, 2·14 ins. in 24 hrs.; East Grinstead 1·80 ins. in 1½ hrs.

Banstead, 3·59 ins. in about 90 mins.; Wallington, 2·77 ins. in 65 mins., and 3·50 ins. in 60 mins.; Wimbledon, 1·58 in. in 80 mins.; Croydon, 1·85 in. in 2 hours 48 mins., and 0·8 in. in 15 mins.; Ponders End, 1·05 in. in 19 mins.; Birmingham, 1·04 in. in 27 mins.; Burnham, 1·73 in. in 40 mins.; a fall of 1·2 in. in 15 mins. seems to be the quarter-hour record for the British Isles.

Heavy Station Rainfalls, Canada and United States.

Toronto, 0·5 in. in 10 minutes; and 0·6 in. in 15 mins.; New York, 1·2 in. in 10 mins.; Philadelphia, 1·6 in. in 20 mins.; Chicago, 0·97 in. in 7 mins.

Heavy Station Rainfalls in or near the Tropics.

Central America, 0·6 in. in 10 mins.; 1·1 in. in 30 mins.; 1·7 in. in 60 mins. Panama Isthmus, 6 ins. in 95 mins.; 4·9 ins. in 60 mins.; 5·86 ins. in 60 mins. Philippines, 27 ins. in 24 hours, also (1913) 48 ins. in 48 hours, and 24 ins. in 8 hours (same storm). Manila, 17 ins. in 15 hours. Near Johannesburg, 3·2 ins. in 15 mins. Near Durban, 15·6 ins. in 15 hours; 17·6 ins. in 24 hours; 6 ins. in 3 hours. Mauritius, 18 ins. in 24 hours, and the mean of 15 stations 9·86 ins. in 24 hours; 99 ins. in 6 days; 24 ins. in 24 hours. Ceylon, 21 ins. in 24 hours; 8 ins. in 4 hours.

In 2 days: Santa Cruz, Teneriffe, 12·58 ins.
In 24 hrs.: Newlands, Cape Peninsular, South Africa, 16·5 ins.
In 12 hrs.: Beaumont, Texas, 13·54 ins.
In 8 hrs.: Santa Cruz, Teneriffe, 3·47 ins.
In 4½ hrs.: Beaumont, Texas, 12·76 ins.

Heavy Station Rainfalls in India.

Madras, 4·95 ins. in 3 hours; 2 ins. in 18 minutes; 3 ins. in 60 minutes, 10, 11, 12, 13, 18, and 20 ins. in 24 hours. Madras Presidency (South Arcot), 7, 8, 9, and up to 11·3 ins. in 24 hours. Central Provinces (Talgaon), 7·75 ins. in 6 hours. West Coast, Bombay Presidency, 8 ins. in 2 hours. Bombay Town, 7 to 9 ins. in 24 hours. Sholapur, 10 ins. in 7 hours.

Forests and Rainfall.

In a considerable number of cases it has been shown that the removal of forests has been followed by a diminution in the rainfall, and in other cases the rainfall has increased with the extension and growth of the forests. The extent of the difference probably depends upon whether the coolness of the forest area just turns the scale in favour of rain at critical times, the resulting increased coolness and dampness causing further falls of rain; or whether, on the other hand, the forests merely present the best conditions in areas where the conditions generally are favourable to steady rainfall at frequent intervals. A point which is often overlooked is the effect of trees in increasing the total precipitation considerably beyond that recorded by rain gauges. A large proportion of the rime which collects on the twigs of trees in frosts afterwards reaches the ground as water, and, in climates such as those of the British Isles, the total amount of water deposited on the twigs from fogs and drifting clouds is considerable, and most of it reaches the streams or underground storage, or at least replaces losses from subsequent rainfall.

Of more importance, however, to hydraulic engineers is the effect of woodlands in modifying the run-off. The rush of water from bare hillsides is exchanged for the slower delivery from the matted carpet of the woodland, losses by evaporation may be much diminished and the melting of snow usefully retarded. In catchments from which flood waters are largely lost, woodlands may increase the available run-off by extending the period of surface flow. The maximum floods of rivers are reduced, and the lowest summer flow increased. Woodlands are usually much more effective than minor vegetation, such as gorse and heather, in preventing the soil from being carried from the land into an open reservoir.

To protect a reservoir from silting, it may be unnecessary to plant large areas, the silt being arrested by suitable planting of narrow belts of woodland, or by the protection of natural growth, along the margins of the streams.

Some engineers consider that in the case of small reservoirs the shelter afforded by a belt of trees along the margins is of value in reducing the amount of scour of the banks caused by wave action. Afforestation over considerable areas in large river basins would, in many cases, reduce the amount of silting in navigable rivers and estuaries.

A matter which does not receive sufficient attention in connection with hydraulic engineering is the effect of judicious planting or woodland conservation over small areas. A narrow belt of woodland along the foot of a slope will arrest the soil brought down by rains from the hillside. The encouragement of dense vegetation along the bottom of a narrow valley or glen may check the rate of flood discharge to a useful extent. The planting of suitable trees along ridges, and for a little way down the slope facing the rain bearing and damp winds, will produce the maximum of certain desired effects, in proportion to the area occupied. Suitable tree and bush growths in swampy areas and around their margins will increase their effect in checking flood discharge, and may prevent these areas from contributing large quantities of silt to the streams during very heavy rains. Areas of soft, cultivable soil liable to denudation may similarly be protected. Generally, a country which is, in the ordinary English sense of the words, ‘ well-timbered ’ is, from the point of view of the hydraulic engineer, a favourable country ; and in the development of new lands the future effects of a proposed agricultural policy should be considered from this point of view, and in consultation with hydraulic engineers.

Rain Gauges.

The smallest diameter for a serviceable rain gauge is 5 ins., and is the size generally used. Trials with gauges of various diameter ranging from 1 in. to 2 ft. have shown that if they are set perfectly level, and observed with great care, exactly the same rainfall has been registered by all of them.

The standard height above ground for rain gauges is 1 ft.

The higher a gauge is fixed above the ground the smaller is the quantity of rain caught, owing to the eddies carried by the wind about any prominent upstanding object. The curve diagram (fig. 1), given in Beardmore’s Hydrology, gives the divisor to be used for increasing the

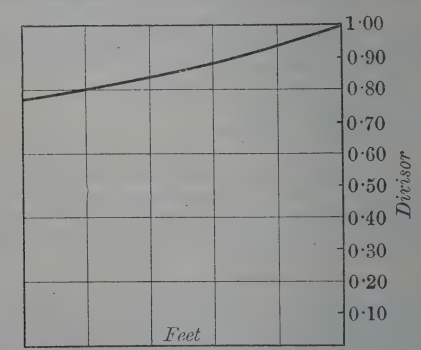

FIG. 1.

quantity of rain observed at any given height above ground level, so as to make the observation equal to that at ground level.

It is more important to have rain gauges placed at a uniform height above the ground than to have them of uniform diameter.

Available Power from Rainfall.

In terms of *average* values of rainfall, catchment area, and head, the available power can be expressed :—

$$\text{H.P.} = 0{\cdot}00828\, f\, m\, h\,;\ \text{E.H.P.} = 0{\cdot}0073\, f\, m\, h\,;\ \text{kW} = 0{\cdot}0062\, f\, m\, h\,;$$

where

f = average rainfall in inches ; m = catchment area in sq. miles ; h = average head in ft.

Example :—The catchment of the Lochaber water-power scheme is 303 sq. miles ; the average annual rainfall is 73 in. ; and the average head of water available near Fort William is 742 ft. What will be the theoretical power ?

$$\text{H.P.} = 0{\cdot}00828 \times 73 \times 742 = 136{,}000\ \text{H.P.},$$

and, as 1·0 H.P.-year = $1 \times 8{,}760 \times 0{\cdot}746 = 6{,}535$ kW-hours, the output (theoretical) would be

$$6{,}535 \times 136{,}000 = 888{\cdot}76\ \textit{million kW-hours.}$$

(*W. T. Taylor*, '*The Electrical Review*,' *October* 12, 1923.)

WELLS.

(Contributed by W. H. Booth, F.G.S., M.Am.Soc.C.E.)

The back of the steining should be puddled to a depth of 12 or 15 feet, so as to make the water pass through a considerable amount of soil before entering the well.

The ground around should be puddled, sloped away from the well, and paved, and the lining carried up about 2 feet above the ground level, to keep all dirty water out of the well. The mouth should be covered over and the water drawn by a pump rather than a bucket.

Form of Wells.—Generally circular, but when there is no steining or a large water-yielding surface is required, as in headings driven from the shaft, a rectangular, elliptical, or other form may be used. Ordinary wells have a clear diameter of from 4 to 5 feet, but when very deep may require to be made large enough at the top to allow of reductions as the depth increases, still leaving room enough below for any pumping machinery.

Temperature in deep wells increases about 1° F. for every 55 feet in depth below 60 feet, at which depth it is pretty uniform at 50°.

Tubing for bore-holes is sometimes of cast iron, the lengths being held together by wrought-iron collars fitting over the ends and flush with the outside of the tubes.

The approximate average cost (pre-war prices) in England may be taken at 1*s.* 3*d.* per foot for the first 30 feet, 2*s.* 6*d.* per foot for the second 30 feet, and so on, advancing 1*s.* 3*d.* per foot for every additional 30 feet in depth. This does not include cost of tubing, conveyance of plant and tools or working in rock of unusual hardness. (See also Artesian Wells, page 1471.)

STEINING.

This is lining the well, chiefly to keep the sides from falling in. Where bricks are not available stone may be used, and even timber, but the latter soon decays. Iron cylinders are also employed.

Brick Steining.—The bricks should be hard, well burnt, and well shaped. Malm paviors are very good ; if stocks are used, they should be very carefully picked. The bricks are either laid dry, called '*dry steining*,' or in cement, or good hydraulic mortar, where strength is required or to keep out water.

In cement work cast-iron curbs are sometimes built in at suitable intervals, to facilitate the execution of the well, and also to strengthen the work.

In dry steining one or two courses set in cement are introduced for strength at intervals varying mostly from 5 to 12 feet.

The bricks are laid flat, breaking joint. The thickness of the steining varies with the depth and diameter of the well and the firmness of the ground ; from 9 inches for diameters up to 9 feet, to 14 inches for diameters up to 14 feet, with an extra half-brick in very bad or loose soils. The best method of laying them is in half-brick rings, with headers at intervals, tying them together. Courses of headers are objectionable, unless the diameter of the well is large.

To exclude land or other springs not under very great pressure, concrete or clay puddle is introduced behind the steining ; clay puddle is the more certain to be watertight. When the bricks are laid dry, the swelling of the earth behind will gradually fill up the spaces between them. It is very essential that the steining should be well backed up by working as close as possible to the sides of the excavation ; and wherever, from any irregularity in the excavation, this is not convenient, the space should be well filled in either with puddle or brickwork ; the latter is preferable, especially where a slip of earth has taken place, in which case the brickwork should be laid in cement. The principal object is to prevent the steining failing by being forced in at one part and out at the other by the pressure of the ground.

The ground round a well should be waterproofed for 30-feet radius of a circle about the well. This ensures that no water can even reach the back of the steining, which has not passed through a considerable bulk of earth.

Well-Sinking.

There are two methods of sinking and steining wells, the first adapted to dry or firm, and the second to wet or loose, ground.

First Method.—The excavation being sunk to a safe depth, a curb or ring of timber is placed at the bottom, formed in two or more thicknesses and lap-jointed to equalise its strength, cut circular on the inside but not on the out, of a breadth sufficient to receive the brick-lining of the well, and not less than 3 inches thick. On this, truly concentric with a central plumb-line, the brick lining is built up to the surface, the earth or a puddling of clay being punned in hard round the outside as the work rises. The excavation is now resumed in the centre, leaving enough earth undisturbed under the curb to support the work done. When a safe depth is again attained, the earth under the curb also is often removed in four equidistant places, the duty of support devolving temporarily on the intermediate portions left as piers; and from a broad central footing of timber 4 raking struts are set up and firmly fixed, to support the curb in the points from under which the earth was taken. This being done, the piers of earth are dug away, and the bottom is then, as before, made level around as a bed for a second curb; and thus the work proceeds in stages down to the required depth, the projecting angles of the curbs outside, by their penetrating the soil, contributing to the support of the brickwork in its progressive extension downwards. Sometimes the curbs, instead of being propped from below, are suspended by cross-timbers from the mouth of the well by iron rods.

Second or Older Method.—The surface of the ground having been levelled, or an excavation made to a safe depth, an iron curb with a sharp lower edge, or a wood curb shod with iron, with an outer diameter equal to that of the brickwork cylinder, is laid on the surface or in the excavation, and as the brick steining is built upon it, it sinks by its own gravity, the bricklayer continuing building up at the surface, while the digger inside descends, the soil being hoisted out as fast as excavated. When from the swelling of the ground the descending work becomes earth-bound, the process has to be recommenced at its base to a smaller diameter.

Iron Cylinders are sunk as just described for brick cylinders. They are mostly inserted in order to continue the well when the brick steining has been interfered with by running sands or the irruption of water. Until the water-yielding stratum has been passed through, the sinking of the cylinders is carried on with the assistance of the ordinary boring tools. The cylinders are generally of cast iron, made up of 5 or 6 feet lengths, bolted together by means of internal flanges, leaving the exterior surface perfectly smooth. The bottom length has, instead of a lower flange, a cutting edge to facilitate the descent. The joints are made watertight, either with gasket soaked in tallow or by being caulked with iron cement. Wrought-iron cylinders used for steining are jointed with angle and T iron by rivets countersunk on the outside, so as to leave a smooth surface. When the cylinders become earth-bound they are loaded, or else pressed down by jacks or rammed down by wooden 'dollies.'

Quantity of Water in Wells.

To ascertain the quantity of water in a well, take half the circumference (in the clear) and multiply by half the diameter; multiply the result by the depth, which gives the cubic measures, then reckon 6 gallons and 1 pint to the foot cube.

To Increase the Yield from a Well already Executed.

1. The water-level in the well may be lowered by pumping, etc., by which the hydraulic depth for the inflow is increased.

2. The bore-hole may be deepened, thus probably leading to denser strata, through which there would be less percolation, and thus more yield to the well.

3. Headings may be driven laterally from the well; the best level for them is just above the lowest level to which the water is ordinarily pumped; in plan they should be straight lines through the well.

4. Dynamite or other explosive is lowered down to the bottom of the bore-hole, and then exploded by electricity.

Protective Distance from Drains.

A well should not be closer to a drain than 4 feet for every foot in depth; thus a 20-foot well should be at least 80 ft. from any possible source of corruption. Wells 100 ft. deep, if with water-tight sides, may be relied upon as safe from leakage contamination, as this depth of soil is capable of removing a greater amount of organic matter that may exist in the water.

Prof. Frankland gives 200 yards from a cesspool, cemeteries, etc., as the nearest safe distance; in Italy, 100 yards; in France and Austria, 200 yards. But much will depend on the dip and nature of the strata.

Artesian Wells.

In the best modern practice, artesian wells are lined with stout steel-socketed wrought-iron or steel pipes, to a point at least lower than the lowest water level. In chalk bores the pipes are lightly driven at least 10 feet into the chalk—or further, if necessary—the projection of the sockets being very effectual in securing the shutting off of the upper, and perhaps undesirable, waters from the lower.

No pipe should be less than $\frac{1}{4}$ inch thick, from 3 to 6 inches diameter, up to $\frac{3}{8}$ inch thick for pipes of 10 to 16 inches.

When the water level is considerably below surface, the yield of a well is measured by the capacity of the largest pump that can be put down the bore tube. Deep-bore pumps consist simply of a plain barrel hung in the water by a wrought-iron rising main pipe of slightly greater diameter. The bucket is hung by rods inside the rising main, and these project through a stuffing-box in an outlet casting on the top of the main, and are actuated by a crank or other means to give a stroke of 18 to 24 inches in ordinary cases. A plunger is added in the outlet casting for forcing to considerable heights above surface, and a balance lever should be connected to the cross-head by links.

The best water-bearing strata in England is the Lincolnshire (Oolitic) limestone, which contains many spouting copious wells; notably one at Sleaford, only 6 inches diameter, which overflows at 30,000 gallons per hour 3 feet above surface. The chalk is very free bearing in many parts, but capricious and occasionally nearly dry. The Keuper marl yields good brewing water at Newark, Burton, Leicester, etc., but not very copiously, and apt to be very small in amount and capricious in character. The Keuper sandstone is a free yielding stratum, and gives good soft water. The Permian sandstone is also a fair and at times a copious water-bearing rock, and so also is the magnesian limestone.

The Lower Greensand sometimes yields copiously, and, as a rule, the more copious the supply, the better the quality. It is at times ferruginous. The Lias clay is apt to produce saline water; so also is the London clay. The Upper Tertiary beds of the London basin below the London clay often yield fair but slightly alkaline supplies.

The carboniferous rocks vary greatly, and often give copious supplies, and but few rocks are quite dry. As a rule, the more copious yields are all within 200 feet of the surface. Deeper boxes yield less and less. Water has been obtained from the Lower Greensand in Windsor Forest at 1,243 feet below surface, the quantity being small, the quality good, and the water rising to about 230 feet above sea level, or overflowing the surface nearly 8 feet.

For borings in rock having a surface outcrop near the site of the boring, the water level will usually be little or nothing above the nearest watercourse crossing such outcrop, but where borings penetrate an impermeable surface, and reach a rock having a distant outcrop, the water level will be determined by such outcrop, and, though lower than the receiving surface, will be higher than a distant draining point, if any.

It is by no means unusual for well borers to pass through water and declare it to be absent. They will also continue boring into strata that are hopeless as water-bearing strata under the impression that they have not yet passed through the upper stratum. Thus in places the Gault way rests upon the Kimmeridge clay, and it is difficult to distinguish one clay from the other. Well boring should only be carried out under educated inspection, and regular samples of everything passed through should be kept, and records of the water level every morning and of any change during the day. Small changes in the material and variations of the water level are often very instructive and significant to the hydrogeologist.

Wells in the lower chalk formation are frequently failures, owing to failure of the workmen to recognise the evidences about them.

While there can be no good done by carrying wells to excessive depths, it is a common experience to find wells that have been sunk only to their high-water mark horizon, so that when the water level sinks the well is dry. This is a frequent occurrence in the lower chalk, in which there is a very wide difference between the highest and the lowest water levels. Wells sunk in high-water periods invariably run dry when the lower-water period approaches.

For the varying strata of the British Isles, and the usually small depths required, the ordinary system of boring with chisels and rods appears to be as cheap as any other. For depths beyond 500 feet the rope is often used. No one system can be adhered to, but rods, ropes, and the diamond must be employed, according to the requirements of each case.

More recent practice is to bore by means of the rotary chilled steel shot system. A plain thick steel pipe is notched at its lower end and rotated upon the rock to be pierced. A quantity of chilled steel shot is fed down the pipe. This gets under the lower end of the pipe by way of the notches, and, rolling on the rock under heavy pressure, comminutes by the intensity of the rolling crushing action. Water forced down removes the groundaway rock, and good cores are obtained. Several feet per day may be bored in hard limestone. The method involves no loss of costly diamonds.

To calculate the rate of flow of an artesian well, a simple plan is to lower a bottle of aniline fluid to a depth of, say, 500 feet, and then electrically explode a cap to burst the bottle. The time required for the fluid to appear at the surface gives an accurate gauge as to the velocity of flow. It is claimed that this method gives results as accurate as a weir. The diameter of the pipe being known, the rate of flow readily follows. (*W. H. Booth.*)

WATERWORKS.

(Revised by R. Fairfax Middleton, Assoc.M.Inst.C.E.)

MASONRY DAMS.

Rankine gives for low masonry walls to retain water that the thickness at the base should be about $\frac{4}{10}$ of the height either for rectangular walls or for those of trapezoidal form where the thickness at the top is $\frac{1}{4}$ that at the base.

Another rule for low dam walls is: Thickness at bottom 0·7 height; thickness at middle 0·5 height; thickness at top 0·3 height.

For high masonry dams Molesworth gives H = height of dam in ft.; x = any depth below

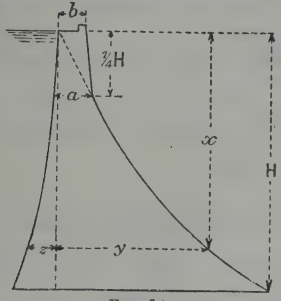

FIG. 1A.

the water surface in ft.; y = offset from vertical line to outer face of dam at any depth x; z = ditto ditto to inner face; b = width of dam at top in ft.; a = width of dam at 1/4H from top in ft.; P = limit of pressure on masonry in tons per sq. ft.

$$b = 0{\cdot}4a; \quad y = \sqrt{\frac{{\cdot}05\,x^3}{\mathrm{P} + {\cdot}03\,x}}; \quad z = \left(\frac{{\cdot}09\,x}{\mathrm{P}}\right)^4;$$

y at any section must not be less than 0·6 x.

In modern practice a common typical section is triangular, the inner face being given a slight batter, and the back a batter which will generally approximate to 1 in 1½ but depends upon the weight of the masonry and the exact form of the wall.

The dam must be so proportioned that the resultant thrust acts within the middle third of the base, both with the reservoir full and empty; this provision should also apply to any horizontal section of the dam. The theoretical apex of the triangle must be high enough to allow, if necessary, for the water overtopping the wall, also for wave action.

EARTH DAMS.

The top width may be anything from 6 ft. to 20 ft., depending on the height of the dam and the freeboard.

The inner slope will generally be about 3 to 1 for gravel or other good material, but with clays it may not stand at this and must then be made flatter.

The outer slopes may be as steep as 2 to 1 depending on the angle at which the material will stand; the outer slope should be well drained. The inner slope must be protected from wave action; this is generally done by laying stone pitching or concrete slabs on the surface of the bank.

Watertightness is generally obtained by means of a core of puddled clay in the centre of the bank, the puddle being carried right down through the solid ground below the bank and well bonded into the impervious material on which the reservoir is built.

The puddle wall should generally be about 4 ft. thick at the top and both sides batter outwards about 1 in 40 to ground level, below which the thickness of the puddle should be quickly reduced to about 6 ft. and carried down at this as far as necessary. This applies to good puddle; the thickness must be increased if the puddle is of poor quality.

The puddle is sometimes replaced by a concrete wall; care must, however, be taken to avoid the possibility of unequal strains upon such a wall, as these might lead to cracking and possible failure.

Another method is to fill the trench in the solid ground with concrete and to build on this a wall of puddle. In this case the puddle must be well tongued into the concrete so as to ensure a watertight joint.

The François Cementation Process (*The François Cementation Co., Ltd.*) has been successfully employed for the injection of dam foundations to render them watertight, thus considerably reducing the amount of required excavation and the necessity of masonry aprons: e.g. the Mazoe Dam, in South Africa. (*A. H. Krynauw, Engineering Society of South Africa, May* 18, 1918.)

The same process is employed with equal ease and efficiency to seal off leakages making through existing dams and reservoirs: e.g. Stobshiel Reservoir, Scotland; Upper Booth Dam, near Halifax.

See also 'Shafts,' Section XXXIX.

Lining Distribution or Service Reservoirs.

In small reservoirs watertightness may be obtained by covering the whole of the bottom and sides of the reservoir with a layer of puddle. The puddle in this case should be covered with concrete to protect it from damage. In reservoirs of any size, however, the cost of the method would be prohibitive.

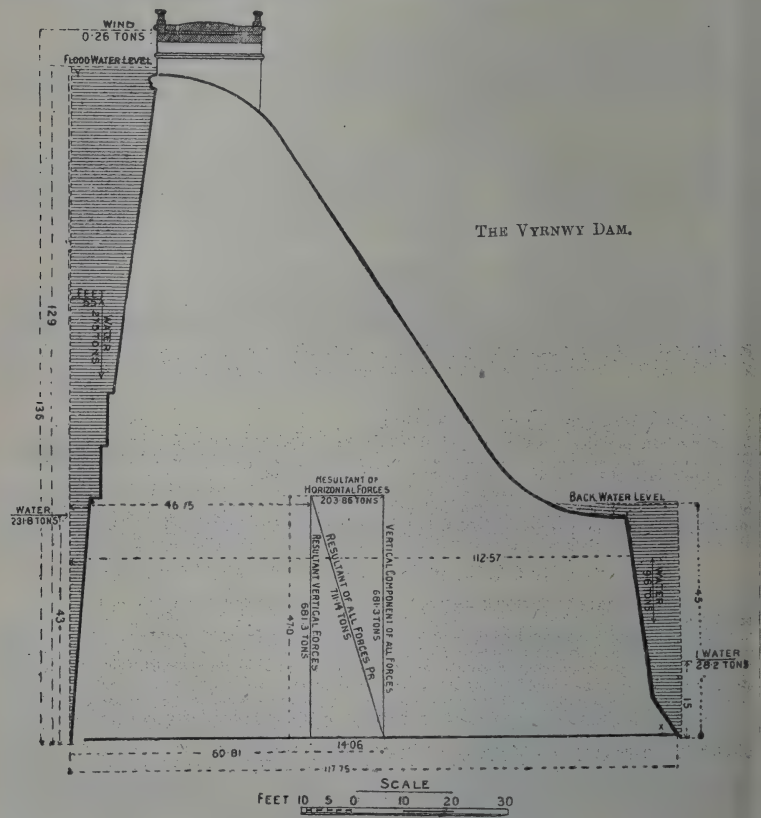

FIG. 2.—Cross-section of Vyrnwy Dam.

CALLENDRITE.

Callender's 'Callendrite' (*Geo. M. Callender & Co. Ltd.*, 25 *Victoria Street, Westminster, S.W.* 1) is the original bitumen damp course (for damp-proofing buildings) and sheeting, for effectively waterproofing old and new reservoirs, tanks, swimming baths, basements, flat roofs, etc., as

CALLENDER'S SHEETING.

TRADE 'CALLENDRITE' MARK

For the PERFECT WATERPROOFING of

RESERVOIRS, PONDS, CONDUITS, SWIMMING BATHS, TANKS, AQUEDUCTS, BRIDGES, EJECTOR CHAMBERS, ROOFS, BASEMENTS,

Etc., etc.

'CALLENDRITE'

is the ORIGINAL PURE BITUMEN SHEETING invented by CALLENDER'S over **50** years ago, and is guaranteed to be manufactured from the finest Bitumen obtainable for the purpose, properly refined and tempered under **CALLENDER'S ORIGINAL PROCESS.**

F. 1475

invented by Callender's over fifty years ago. It is used by the Admiralty, the War Office, the Office of Works, the London County Council, and other bodies.

The sheeting—for all engineering work—is made in standard rolls, 24 ft. long, 6 ft. wide. Damp course in rolls 24 ft. long, to all the usual wall widths. When necessary, Callender's Patent Impervious Wall Ties and Patent Joining Irons should be employed. Price of Callendrite (including free delivery for fair order) averages 3½*d.* per foot super for damp course and 5*d.* per foot super for sheeting. Inclusive price given, with guarantee of efficiency for laying and fixing sheeting by Messrs. Callender's own workmen.

THE CROTON DAM.

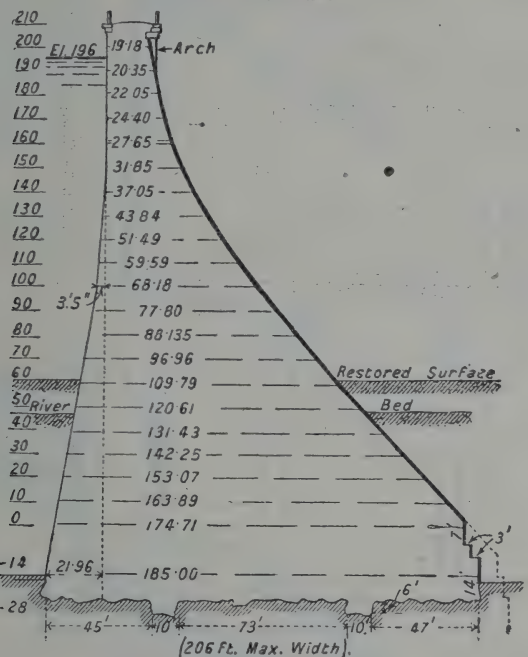

FIG. 3.—Cross-section of Croton Dam.

THE VYRNWY DAM.

The Vyrnwy Dam (fig. 2) is 1,350 feet long on the top, the plan being straight. The maximum height above the foundation is 136 feet. The profile adopted is designed to resist the water pressure and also to form a waste-weir; the front face of the wall is, therefore, made to conform to the curve described by water in overflowing, and to deflect it into the basin in front of the dam. The foundation is laid on a clay slate rock. The dam is built of 'Cyclopean rubble,' the stones varying in weight from 2 to 8 tons. For the lower part of the dam the stones are set in mortar composed of 2 parts washed sand, 1 part Portland cement; in the main portion of the work, instead of plain sand, a mixture of 1 part of the latter with 2 parts pulverised quarry rock was used for making the mortar, 2½ parts of the mixture being mixed with 1 part Portland cement. The area of the section, shown by fig. 2, is 8,972 square feet. With the reservoir full and the wind blowing with a force of 60 lbs. per square foot, the maximum stress on the masonry is 6·36 tons per square foot. Where the bed rock has the lowest elevation there are 26 drains in a length of 198 feet of the wall; these drains are 9 to 12 inches square, and lie on the rock near such places where leakage is apt to occur; they are 25 feet from the front face and 30 feet from the back face, and connect with a central tunnel 4 feet high by 2½ feet wide, which traverses the foundation longitudinally at an elevation of 46·3 feet above the base of the cross-section. By means of a cross-tunnel leading down-stream any water that may filter into the foundation above the elevation of the drains is discharged at the front face of the dam.

The Assuan Dam.

The Assuan Dam, fig. 5, p. 1476 is a granite rubble masonry structure founded on a similar rock which is traversed by dykes of softer igneous material. It is situated at the head of the first cataract of the Nile.

As originally constructed it was just under two kilometres in length, the top level of the structure was RL. 110·00, the water being held up to a level of 106·00.

It is pierced for the greater part of its length by sluices which are closed by steel gates, most of them working on the Stoney principle. There are 180 sluices in all, of which 22 are at a level of 100·00 and 18 at 96·00; these sluices are 3½ metres high by 2 metres wide. Of the others, which are 7 metres high by 2 metres wide, 75 are at RL. 92·00 and 65 at RL. 87·50; 30 of the lowest sluices are lined with cast iron, the rest smooth-faced granite ashlar.

The original dam was finished in the summer of 1902.

It was found that the rush of water through the sluices was such as to erode what had appeared to be solid rock, and it was therefore necessary to build masonry aprons along practically the whole length of the pierced dam.

Between 1907 and 1912 the dam was raised so as to impound water to a level of 113·00 metres, and it was at the same time thickened by a blanket wall five metres thick on the downstream side.

The original reservoir impounded 980,000,000 cubic metres of water, or 216,000,000,000 gallons.

The heightened reservoir contains 2,420,000,000 cubic metres, or 533,370,000,000 gallons.

The reservoir is used for irrigation purposes.

GENERAL ARRANGEMENT OF RESERVOIRS.

In reservoirs filled by gravity a waste weir must be provided to carry off flood water, and should be so designed that the maximum flood will not cause the water to rise more than 18 inches over the lip of the weir.

The waste weir channel should be built in solid ground: it is generally constructed in a flight

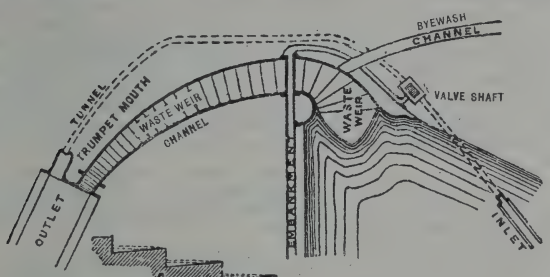

Fig. 6.

of steps, so as to check the velocity of descent; the risers vary from 1 ft., which is best, to about 5 ft., and the tread should, if possible, be at least double the riser. The best form is a series of weirs and pools, or tumbling bays, or flights of steps with long landings or pools at intervals, the drop into pool being as small as possible. The pools may be formed as shown at A (fig. 6): depth of pool = drop, length of pool = drop × 10.

Fig. 6 shows a tunnel round the flank, also the valve shaft, byewash, and other accessories.

The tunnel and byewash are used for passing storm waters during construction, the former being used afterwards for supply purposes and the latter for passing turbid water in times of storm.

Storage Reservoirs.

The capacity of storage reservoirs is arrived at from the formula

$$C = \frac{500}{\sqrt[3]{R}},$$

where,

C = number of days' storage, = R available rain in inches, as explained under heading 'Gathering Grounds.'

Messrs. W. J. E. Binnie and H. Lapworth have lately suggested the following formula for calculating storage:—

$$s = 15\frac{(n-d)^2}{r^{1\cdot85}},$$

where,

s = inches of storage required to supply (constantly from a stream) n inches per annum; d = the extreme minimum dry-weather flow reduced to inches per annum; r = mean run-off, also in inches per annum.

The storage required in gallons is equal to $s \times$ area of gathering-ground in acres $\times$ 22,610.

The formula is empirical, and was arrived at by a study of the data of seven areas of supply.

GATHERING GROUNDS.

In arriving at the water available from an area the average rainfall on the area must be found from rainfall records; ¾ of this is then generally taken as the average for the three driest consecutive years and then a deduction must be made for evaporation, generally 14 to 16 inches; the remainder, subject to special conditions, will be the available rain; ⅓ of this often has to be given in compensation.

The above applies to ordinary cases in the United Kingdom. For a study of run-off under various climatic conditions, see 'Rainfall' (p. 1461).

On the moorland gathering-grounds supplying Sheffield, rainfall averages 40 ins. a year, two-thirds of which is reckoned on as available; one-third goes as compensation to millowners, etc., and one-third to inhabitants. Every 1,000 acres is said to give an average of 1,250,000 gallons per diem. On the Leeds moorland gathering-grounds ¼ cubic feet per second, or 134,600 gallons per diem per 1,000 acres, is the usual minimum dry-weather discharge; the formation is millstone grit, rainfall 26 ins. to 45 ins., of which 14 ins. is allowed for evaporation and 6 ins. as compensation to millowners.

FILTRATION.

(Contributed by H. F. Rutter, M.Inst.C.E.)

Filtration should be preceded by sedimentation. The researches of Dr. A. C. Houston prove that prolonged storage not merely reduces enormously the ordinary and harmless bacterial contents of river waters, but that such storage is a complete protection against danger from pathogenic microbes in the case of water initially infected with such germs.

The area of sand surface needed per million gallons per diem varies considerably, according to the character of the water and the fineness of the filtering medium. Yields of from one million to two million gallons per acre are common values. Modern filters have four feet of water over the sand, two feet nine inches of sand supported by eight inches of graduated shingle. Care should be taken that the uppermost layer of shingle should consist of stones less than half the size of a pea, so as to avoid the danger of the sand being drawn through the shingle. The means of collecting the water should cover the whole floor of the filter and should not consist of transverse pipes placed at intervals. A satisfactory and inexpensive method is to cover the floor with transverse rows of bricks laid dry end to end with a space of 4½ inches between each two rows. These are then completely covered with bricks laid dry at right angles to the rows. A series of 4½ in. by 3 in. channels are thus formed, which lead the filtrate to the central channel made below the floor.

A Deacon meter on the outlet pipe forms a useful means of checking and recording the rate of flow of the filter. Float gauges should be provided to show the relative levels of the water over the sand and in the outlet pipe. The difference between these levels indicates the head under which the filter is working. This head may vary from one inch when the filter is started slowly after cleaning, up to 2 or 3 feet.

Means should be provided for drawing the raw water from above the sand to waste, in case it be required to clean a filter immediately which has become clogged. A quarter to half an inch of sand with the matter arrested thereon is removed by flat shovels. This sand can be washed and spread again either at once, or after the depth of the sand has been reduced by five or six successive cleanings. The cleanings may be at intervals of from one week to four months, according to the character of the water, and the amount of algal growth in the water, which latter condition may materially affect the life of the filter. The removal and cleaning of the main body of the sand is needed at very rare intervals. Filters are in use yielding water of perfectly satisfactory bacteriological character in which the main body of sand has not been changed for forty years.

When a filter is to be cleaned the water should not be drawn down in the sand to a level more than 12 inches below the surface of the sand. This leaves the surface quite hard enough to support the weight of the cleaners, and prevents the sand becoming unduly compacted.

All sensible suspended matter is arrested on the surface of the sand of a filter, and the largest elimination of bacterial life takes place at or near the surface. The bacterial contents are, however, still further reduced progressively in the passage of the water through from five to ten inches of the depth of the sand.

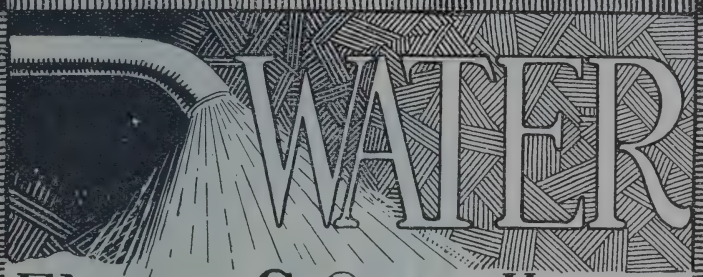
THE 'TORRENT' FILTER.

(The Pulsometer Engineering Co., Ltd., Reading.)

With this plant (fig. 7) the filtration is effected by passing the water under pressure through a certain thickness of suitable filtering medium, arrangements being made so that the entire filtering medium can be thoroughly cleaned.

The construction is very substantial, all parts are accessible, and the various valves for operating and cleaning the filter are brought together at one point for convenient handling. There are no mechanically operated components either inside or outside the filter, so that there are no parts to wear or keep in adjustment.

The filter is made either cylindrical or square (the latter when it is necessary to economise space or when the filter has to be brought in parts into an existing building through ordinary doors). A strainer plate is fixed near the bottom of the filter casing, and this plate carries



Filtration-Softening-Heating

United Water Softeners Ltd. specialise in the purification and treatment of water for **all** *purposes.*

If you have a water problem, it will pay you to submit it for free investigation and report.

Write for Catalogue dealing with the particular treatment you are interested in.

UNITED WATER SOFTENERS LTD.

LASSEN-HJORT & PERMUTIT SYSTEMS

Aldwych House, London, W.C.2.

F.1478

FILTRATION PLANT, TREATING FOUR MILLION GALLONS OF THAMES WATER DAILY

Installed for the Gas Light & Coke Co., Beckton, by

UNITED WATER SOFTENERS, LTD. (Lassen-Hjort & Permutit Systems), ALDWYCH HOUSE, LONDON, W.C. 2.

F. 1479

layers of graded filtering medium. The unfiltered water admitted to the upper part of the filter percolates through the filtering medium, where the matter in suspension is retained, and reaches the space below the strainer plate in a clear and bright condition. The bottom of the filter casing is connected to the filtered water main.

The cleaning of the filter is effected by means of air agitation and a reverse flow of filtered water. If there is sufficient pressure in the filtered water main, say equal to 10 to 15 ft. head,

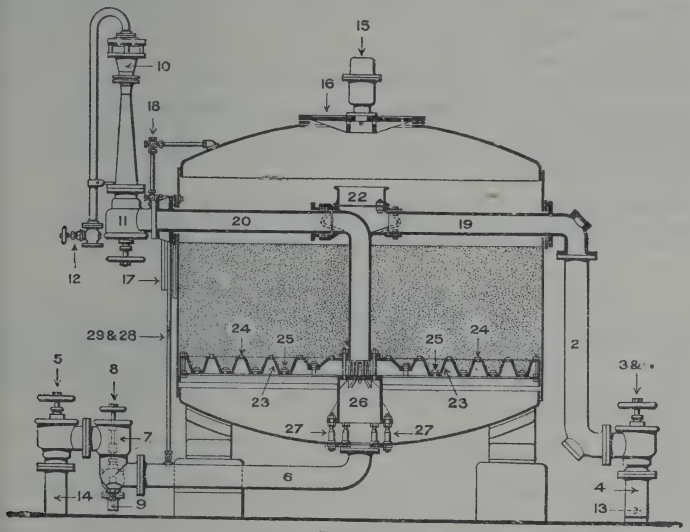


FIG. 7.

a reverse flow from the filtered water main can be used; but if there is not sufficient head in this main, or if the filtered water reservoir is below the level of the filter, it is necessary to employ a centrifugal pump to force the washing water through the filter.

The agitation (by compressed air) is effected by means of a separate system of air nozzles in the strainer plate, through which the air is equally distributed over the whole area of the filter bed. The air nozzles being entirely separate from the strainers make it possible to use the air simultaneously with the reverse flow of water during the process of cleaning, if found

LIST OF COMPONENT PARTS.

1. Unfiltered water inlet valve.
2. Unfiltered water inlet and wash-out bend.
3. Wash-out valve.
4. Wash-out pipe.
5. Filtered water outlet and wash water inlet valve.
6. Filtered water and wash water bend.
7. Patent wash water regulating valve.
8. Drain valve.
9. Drain pipe.
10. Air blower.
11. Blower valve.
12. Steam stop valve to air blower.

14. Filtered water pipe.
15. Automatic air escape valve.
16. Manhole cover.
17. Differential mercury gauge.
18. Water gauge glass.
19. Internal inlet and wash-out pipe.
20. Internal air pipe to strainer plate.
22. Internal wash-out and inlet bell mouth.
23. Strainer plate.
24. Air nozzles.
25. Strainers.
26. Stool for strainer plate.
27. Studs for strainer plate stool.
28. Pressure pipe from underside of filter medium.
29. Pressure pipe from above filter medium.

desirable. The air main is carried above the filter, so that there is no risk of its becoming water-logged, which might cause obstruction to the passage of the air.

A steam blower may be used for supplying the compressed air, but if steam is not available, a small air compressor, with or without an air receiver, can be employed.

The air causes a violent ebullition in the filter and has the effect of raising the filtering medium, so that the various particles are free to move, and in knocking against one another dislodge all the matter which adheres to their surfaces. Whilst the air agitation is going on an upward flow of water carries away, through the wash-out pipe, the impurities which have been dislodged by the action of the air.

This system of cleaning effects a considerable saving in the amount of wash-water used as compared with that necessary when water only, or water and mechanical agitators, are used.

The time taken to clean the filter may be from 10 to 20 mins.—depending on the nature of the water and the time the filter has been at work since the last cleaning. Reference to the diagram on p. 1479 will show that as the nozzles are distributed equally all over the strainer plate and the air has free access to all of them, the cleaning process is as thorough at the sides of the filter as it is in the middle.

A differential gauge is fitted to show the head lost in the filter. This gauge gives an indication of when the filter requires cleaning, because the difference in pressure between the top and bottom of the filter increases as the impurities accumulate on the filtering medium.

MAINTENANCE AND RENEWAL OF WATERWORKS.

In the Metropolitan area, 'pumping' constitutes, on an average, 43 per cent. of the entire maintenance expenditure. During the last thirty years 4,408,846*l.* has been expended out of revenue on pumping operations and on the maintenance and renewals of the pumping-engines and machinery, which during that period have supplied the Metropolis with 1,745,718 million gallons of water for all purposes; thus the cost of pumping alone has been, on the average, 2*l.* 10*s.* 7¼*d.* per million gallons, or ·000606*d.* per gallon.

The cost of repairs and renewals of water-mains and pipes amounted to 2,964,127*l.*, or an average of 1*l.* 14*s.* per million gallons.

The average maintenance cost per mile of water-main or pipe-way (adopting the analogy of a railway as a means of conveyance) has been 24*l.* 5*s.* 5*d.*

The cost per million gallons for filtration is 0·37*l.* (*Price-Williams.*)

Standard of Purity of Water.

Total hardness in practice varies from 0 to 30 degrees; 5 degrees is generally considered best.

Water containing more than the following quantities of impurities should be looked upon with suspicion: Chlorine, 1 part per 100,000; Nitrites, 0·2 part per 100,000; Nitrates, 0·3 part per 100,000; Ammonia, 0·1 part per 100,000; Organic Carbon, 2 parts per 100,000; Organic Nitrogen, 3 parts per 100,000; Albumenoid Ammonia, 0·01 part per 100,000.

WATER TESTING.

Simple and ready tests for rough analysis.

For *Sewage.*—Four drops of a solution of potash (Condy's Fluid) to a small glass of water. The colour turns pale or yellow if decomposed organic matter is present.

Lead.—Six drops of sulphuric acid in small glass of water. White precipitate will be found if lead is present.

Zinc.—Six drops of ferro-cyanide of potassium to small glass of water. Green colour if zinc is present.

Copper.—Eight drops of ammonia in small glass of water. Water turns blue if copper is present.

CHEMICAL PURIFICATION OF WATER.

Water is sometimes purified by chemical means: there are several methods, of which the most important are (1) by the addition of chloride of lime and (2) by submitting the water to the action of ozone.

By these methods the impurities are not removed, but the water is sterilised and all the bacteria which it contains are destroyed.

Reservoirs in which vegetable growth or algæ has become profuse have been cured by dragging a bag of sulphate of copper behind a boat to and fro over the area of the reservoir. A very minute fraction of this poisonous salt will effectually destroy all growth, and it is said that the salt cannot be detected in the water after the process is complete. Apparently the organic matter has absorbed it; but as the salt is extremely poisonous great care must be taken that too much is not used.

Action of Water on Lead.

Peaty water from moorlands has a solvent action on lead pipes, due to acidity. It varies, in terms of a sulphuric acid equivalent, from 1 to 44 parts in 100,000. Peaty grounds of small incline are particularly acid, and such water is dangerous on account of its action on lead pipes. According to Mr. Ackroyd the solvent action would not occur if the acidity did not exceed ·5.

Diameter of Pipes.

The diameters of pipes are usually calculated by either Eytelwein's or Kütter's formula.

Eytelwein's formula is

$$V = \sqrt{(11704\,RS) + \cdot 01698} - \cdot 1303$$

where,

V = velocity in feet per sec.; R = Hydraulic mean radius in feet = Area ÷ wet perimeter = D ÷ l for circular section of pipe, where D = diameter of pipe in feet; S = sine of inclination = h ÷ 4, where h = head in feet; l = length in feet.

An adaptation of this formula which gives good average results is

$$Q = 4 \cdot 7\, D^2 \sqrt{\frac{Dh}{l}}$$

where,

Q = discharge in cub. ft. per min., and D is in inches.

This formula gives rather high results in the case of small pipes with flat gradients, and somewhat low results for large pipes with steep gradients.

Kütter's formula is

$$V = \left[41 \cdot 6 + \frac{1 \cdot 811}{n} + \frac{\cdot 00281}{S} \right] \div \left[1 + \left(41 \cdot 6 + \frac{\cdot 00281}{S} \right) \frac{n}{\sqrt{R}} \right] \sqrt{RS}.$$

where V, R, and S have the meanings stated above, and n is Kütter's coefficient for roughness, which varies from ·009 to ·017, ·013 being a value which is frequently taken.

For new asphalted cast-iron pipes, Barnes (*Inst. C.E. Proc.*, ccxi., Jan. 1922) gives the following formula:—

$$Q = 47 \cdot 087\, d^{2 \cdot 769}\, i^{0 \cdot 529}$$

where,

Q = discharge in cub. ft. per sec.; d = diameter in ft.; i = hydraulic gradient = $\left(\frac{\text{height}}{\text{length}}\right)$.

Incrustation and Corrosion of Iron and Steel Pipes.

High-water velocity is favourable to corrosion and incrustation. Cast-iron being taken to rust at the rate of 100, wrought-iron may be taken as 129, and steel at 133. Some waters, as chalk-well waters, treated by Clark's process, will simply cause a clean layer of carbonate of lime inside a pipe. Upland waters, especially if containing peat acid, cause rust. Old red-sandstone water neither rusts nor causes deposit. Greensand water causes rust. Filtered water is better than unfiltered. Angus Smith composition (see Index) is not a permanent protector. Founders do not as a rule exercise proper care in dipping pipes; the pipes ought to be well brushed out, by passing through them a revolving steel brush *from both ends*, so as to get the brushing effect each way, and they should be then at once heated and dipped. Dipping should be vertical, and the pipes ought to again be brushed by the revolving steel brush when immersed in the dip, without which treatment perfect contact may be difficult to secure between the iron and the composition. It is undoubtedly at the pinholes, caused by minute air bubbles, that the first encroachments of corrosion are made upon the pipe.

According to H. F. Rutter, pipes of cold-blast iron are far superior to those of hot-blast, as regards resistance to corrosion.

Tracing Leakages.

To identify and trace the source of underground water, such as leakages from canals, reservoirs, pipes, etc. :—

Fluorescin.—Mix fluorescin with the supposed source of the leakage. One grain is sufficient to colour 100 tons of water.

Indigo.—One grain of indigo dissolved in sulphuric acid will colour a ton of water.

The coloration is more easily detected by placing the water in a very long test-tube and looking through the latter endways.

Waste Water Detection.

(*The Palatine Engineering Co., Ltd.*)

The detection of invisible leakages between the reservoir and the consumer is usually done by meters of the 'Deacon' type, similar to fig. 8. A large recording meter is fixed on the main

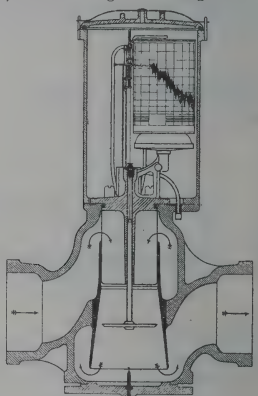

FIG. 8.

at the reservoir. The supplied area is divided into districts of about 2,000 inhabitants and arranged so that the whole supply comes from one direction, and passes through a Deacon meter. Fig. 8A is a plan of the area showing valves.

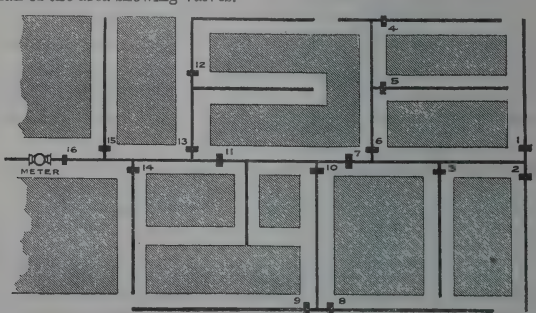

FIG. 8A.

A typical chart for twenty-four hours in an uncontrolled district is shown in fig. 9. The minimum flow during the night is 2,000 gallons per hour (represented by the shaded portion), or 48,000 gallons per day. In the absence of night supplies for trade purposes, this water is leaking through defects. The water used or misused (represented by the cross-hatched portion) is 29,775 gallons, making a total supply of 77,775 gallons per day.

To locate this waste a chart is fitted in which the time scale is multiplied by four. During the night the inspector proceeds to the end of the district and closes No. 1 valve, and the other valves in succession, at about 15-minute intervals, noting the time and the location of the valve.

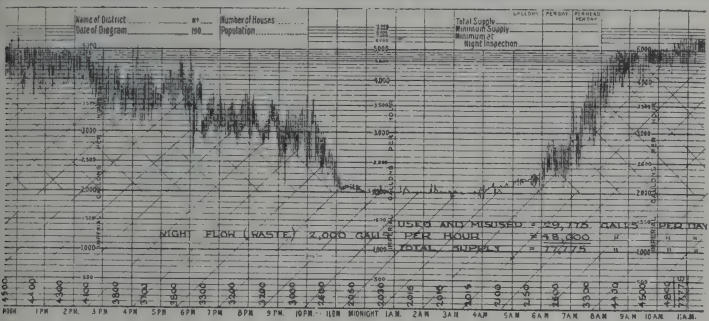

FIG. 9.

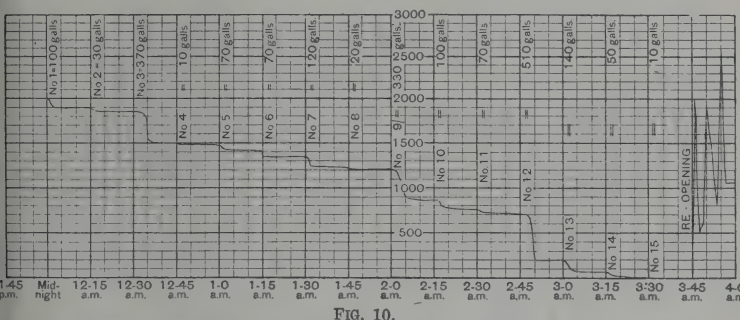

FIG. 10.

The result is shown in fig. 10, the rate of flow in each portion before isolating being clearly recorded. There is an indication of large defects in portions supplied through valves Nos. 3, 9, and 12. These are afterwards traced by a form of stethoscope and examination of fittings.

Consumption of Water.

This varies very largely in different parts of the country: in Edinburgh as much as 40 gallons per head per day are consumed, and in Glasgow much more. Where trade requirements are small 25 gallons per head per day should, however, usually be sufficient for domestic consumption, garden, and street watering, and for flushing.

Hardness of Water.

Hardness is termed *Permanent* or *Temporary* according as the hardness is due to the bi-carbonate of lime and magnesia, which cease to be soluble at 212°, or to sulphate of lime, which remains in solution to much higher temperatures. There exist at the present date two methods of removing either or both of these forms of hardness, the first being by treatment with caustic lime and caustic soda, and the second by filtration over zeolites.

(1.)

Treatment by Caustic Lime or Caustic Soda.

Lime sulphate is dealt with by carbonate of soda, and is converted into the mono-carbonate of lime, while sulphate of soda remains in solution as a very soluble salt. Practically these two lime salts, or the magnesia, are the only salts calling for practical treatment. The following are the reactions which take place, from which it is obvious that where caustic soda can be procured cheaply it may be used where both impurities are present, and will perform a double duty and take the place of some or all of the caustic lime.

(*a*) A water containing only bi-carbonate of lime :

Bi-carbonate of Lime	+	Caustic Lime	=	Carbonate of Lime
$CaO+2(CO_2)$	+	CaO	=	$2(CaCO_3)$
$56+88$	+	56	=	$2(100)=200$ of deposit

(*b*) A water containing carbonate of magnesia :

$$MgO+2(CO_2) + CaO = (MgCO_3)+CaCO_3$$
$$40 + 88 + 56 = 84 + 100$$

(*c*) A water containing sulphate of lime :

Sulphate of Lime		Carbonate of Soda	
$CaSO_4$	+	Na_2CO_3	$=CaCO_3+Na_2SO_4$
136	+	106	= 100 + 142

or water (*a*) treated by caustic soda :

Bi-carbonate of Lime		Caustic Soda		Carbonate Lime		Soluble Carbonate Soda Water
$CaO+2(CO_2)$	+	$2(NaHO)$	=	$CaCO_3$	+	$Na_2CO_3+H_2O$
144	+	80	=	100	+	106 + 18

(*d*) A water with both salts in solution :

$$\{[CaO+2(CO_2)] + CaSO_4\} + 2\{HNaO\}$$
$$144 \qquad 136$$
$$= \text{first reaction } [CaO+2(CO_3)]+CaO+[Na_2SO_4+H_2O]$$
$$= \text{second reaction } \begin{bmatrix} CaCO_3+CaCO_3 \\ \text{insoluble} \end{bmatrix} + \begin{bmatrix} Na_2SO_4+H_2O \\ \text{soluble} \end{bmatrix}$$

Both actions go on simultaneously.

When the bi-carbonate exists in greater proportion than 144 to 136 of the sulphate, the difference in excess must be dealt with by caustic lime as per (*a*). When the sulphate of lime is in excess beyond 136 to 144 of bi-carbonate, the excess is to be dealt with by carbonate of soda as in (*c*). There is no such salt as bi-carbonate of lime except in solution in water containing carbonic acid gas. It is taken as evidence of the existence of the bi-carbonate that the carbonic acid gas is found in the equivalent necessary proportion which would form a bi-carbonate.

(2.)

REMOVAL OF PERMANENT OR TEMPORARY HARDNESS BY FILTRATION OVER ZEOLITES.

The exchange which takes place may be represented by the following formulæ which show the reaction, P representing the zeolite or 'Permutit.'

For the softening of temporary hardness :—

$$P - Na_2 + CaH_2(CO_3)_2 = P - Ca + 2NaHCO_3$$
$$P - Na_2 + MgH_2(CO_3)_2 = P - Mg + 2NaHCO_3$$

For the softening of permanent hardness :—

$$P - Na_2 + CaSO_4 = P - Ca + Na_2SO_4$$
$$P - Na_2 + MgSO_4 = P - Mg + Na_2SO_4$$

The reaction continues for so long as any of the base originally existing in the active Permutit remains, after which all action ceases, and the active base has to be restored to its original state by a treatment with a sodium salt.

Thus by a process of exchange to and fro, which is effected without any wastage in the zeolite itself, a softening action is secured, which is continuous and capable of thoroughly and completely removing all hardness in any water supply. The method of softening water by this treatment of filtering through zeolite affords the only means for complete elimination of both temporary and permanent hardness at one and the same time, a water of zero degrees of hardness resulting for so long as the designed capacity of the plant is not exceeded.

By adoption of zeolytic filtration, it has become possible to entirely remove from a water supply all traces of iron in the water, thereby eliminating to a great degree the high corrosive property possessed by certain supplies.

Softening Water.

Dr. Clark's process softens water rendered hard by calcium bi-carbonate. It consists in mixing with it about one-tenth (for spring water from chalk) of water saturated with lime in solution, the lime in which, combining with the free carbonic acid of the bi-carbonate, forms a solid precipitate of chalk. It will soften Thames and New River water down to $3\frac{1}{2}°$, or lower than if boiled for an hour; but it can rarely bring any water below $2\frac{1}{2}°$ of hardness, what is left being termed permanent hardness. Prolonged boiling will drive off the free carbonic acid from the bi-carbonate, precipitating the carbonate. According to Clark's scale, $\frac{1}{4}$ oz. of soap will remove 1° of hardness from 10 gallons of water.

Note.

The values in the foregoing table are calculated from the formula

$$V = 140\sqrt{rs} - 11\sqrt[3]{rs};$$

where V = velocity in feet per second, r = *hydraulic mean depth* (= area of wet cross section divided by wet perimeter = for full pipes, $\frac{1}{4}$ diameter) in feet, s = sine of inclination, or total fall divided by total length.

For pipes of greater diameter than above divide the proposed diameter by 4, then twice the velocity opposite to the quotient in the table will be the velocity required, or the corresponding supply multiplied by 32 will be the approximate supply in gallons per minute.

Velocity in Feet per Sec. = $8{\cdot}025\sqrt{H}$ ($8{\cdot}025 = \sqrt{2g}$)	Head in Feet (H)	Lbs. Press. per sq. in.	Diameter of Bore in Inches and Area of Bore in Feet.

To find required head multiply length of pipe in yards by factor in table for given pipe and quantity of water required; the result is the head in feet.

EXAMPLE.—Head in feet required to pass 1,000 gallons of water per minute through 30 yards of pipe. In table under 8, and in line with 1,000, will be found ·125; then ·125 × 30 = 3·75. which is feet head required.

The figures in the table are true for plain, smooth, straight pipes. Additional head must be allowed if pipes are at all of a rough nature or broken in contour internally. For each right-angle bend having a radius of about twice the diameter of pipe, and passing the average quantities given in table, about 1½ ins. of additional head must be allowed. (*T. Box.*)

TABLE SHOWING GALLONS OF WATER PER MINUTE CORRESPONDING TO SPEED OF WATER THROUGH PIPES, IN FEET PER SECOND.

(Gwynnes Pumps, Ltd.)

METROPOLITAN WATER BOARD STANDARD SOCKETS (Table, page 1492).

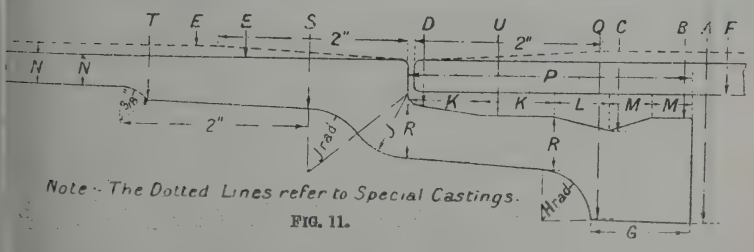

FIG. 11.

The joints of the above standard pipes are made by caulking a ring of lead wire ¼ in. in diameter to the bottom of the socket, then running in molten lead for the remainder of the depth, and afterwards caulking or 'setting up.' Alternatively, lead wool may be caulked in for the whole depth.

Sizes of Lead Pipe are Internal. 1¼ is the usual Minimum Size for Closet Pipe, and 9 lbs. per Yard Minimum Weight.

Comparative Value of Cast-Iron, Wrought-Iron, and Steel Drain Pipes.

Extra heavy cast-iron soil pipes in a number of buildings in nearly all cases had the cast-iron vents evenly pitted on the inside, but in the house drains and branch wastes the lead-caulked joints had opened up more or less. Black steel vents showed scaling to a considerable depth after only 10 years' use. Galvanising was observed to be less of a protection against corrosion on steel pipes than on wrought-iron pipes. The galvanised coating does not adhere so firmly to the smooth surface of steel pipes as to the comparatively rougher surface of wrought-iron pipes. The galvanising on steel pipes showed signs of disappearing within 10 to 20 years. The investigation furnished ample evidence in favour of genuine wrought-iron pipe as a far more durable material for house drainage purposes than steel pipe.

(*W. P. Gerhard, Proc. of the American Soc. of Mech. Engineers.*)

Stoneware Drain Pipes (p. 1422) have the advantage over all the foregoing, in not corroding at all.

Unbalanced Pressures on Bends, etc.

Where any considerable pressure has to be sustained by pipes of large size the unbalanced pressures on bends, etc., must be resisted, horizontally by strutting or tying, vertically by strutting or anchoring. The unbalanced pressure on any bend may be found thus :—

Unbalanced pressure on back of bend = the sum of the areas of the ellipses shown in the elevation × the pressure per unit of area, or $A \times B \times \cdot7854 \times 2P$ = unbalanced pressure.

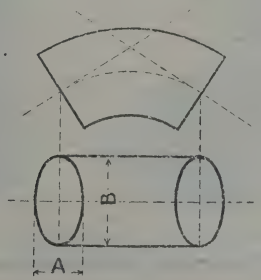

FIG. 12.

WATER TANKS.

Water tanks for house supplies should be covered from the light in order to prevent vegetable growth, but they should be ventilated. A good form of ventilator is an ordinary house sewer air inlet with the mica flaps removed. These should be placed, one or more, according to the size of the tank, at each end of the tank, standing a foot or two above the cover. At one end their openings, which are lateral, should face to, say, the south-west, and at the other end in the opposite direction, so as to set up a flow of air.

The cheapest tanks, to be durable, are excavated partly in the ground, the removed earth being banked against the walls built above ground and rammed at an inward slope so as to afford support against the water pressure. The walls may be of brick or of concrete, rendered internally in good cement mortar. The banks of spoil should be neatly trimmed and sodded or grass sown, and in this way a tank may be almost hidden. Where economy of material is an object, a tank is best circular, since the bank outside can be harder rammed without danger of turning the walls inwards.

These 'tanks' should not be confounded with 'cisterns.'

Steam Meters

The increasing use of Steam Meters in industrial boiler plants is the surest indication of their service.

Economies have been effected through the installation of such meters that have surprised the engineers concerned ; but the wonder is that still there are concerns which do not make use of these money-saving instruments.

METERING AND MECHANICAL TESTING APPLIANCES.

PART I

METERING OF WATER, AIR, GAS, STEAM, AND COAL.

(Contributed by J. L. Hodgson, B.Sc., A.M.Inst.C.E., M.I.Mech.E.)

The metering of fluids is undertaken to enable running costs to be apportioned, sales to be effected on an equitable basis, to control the mixing of reagents in various chemical processes, or to detect wasteful or inefficient use so that working costs may be reduced and unnecessary additions to plant obviated, etc.

Various efficient and accurate types of water and gas meters have been in use for many years; it is only recently, however, that accurate and reliable air and steam meters have been developed. The first large installation of air meters was made on the Rand in 1911, where now more than 300 million h.p. hours per annum are metered, at an ascertained annual aggregate money saving of 130,000*l.**

The following is a brief summary of the principal classes of fluid and gaseous meters, with notes as to their application, and the names of the leading makers:—

1. Meters Based on Volume or Weight Measurement.

(*a*) Tanks or weighing. [For liquids, condensed steam.]

(*b*) Receivers of known capacity discharging between known pressures and temperatures. [For air and gas.]

(*c*) Piston displacement meters. [For water (Messrs. George Kent, Ltd., Luton; Messrs. Beck & Co. Ltd., Southwark, London; Messrs. Frost, Manchester).]

(*d*) Water-sealed drum meters. [For gas (The Gas Meter Co., London).]

(*e*) Bellows meters. [For gas (The Gas Meter Co. Ltd.).]

2. Meters which Measure the Velocity at a Point or Points in the Cross Section of the Stream.

(*a*) Pitot tube meters. [For water, air and gas (Messrs. George Kent, Ltd.). For air and gas (The Rotary Meter Co. (1905), Ltd.) For steam (The General Electric Co. of Schenectady and the British Thomson Houston Co. of Rugby).]

(*b*) Professor Morris's hot wire velocity indicator. [For air and gas (The Cambridge Instrument Co. Ltd., Cambridge).]

(*c*) Impact meters. [For measuring air velocity in mine tunnels (Messrs. Davis).]

(*d*) Anemometer meters. [For water in open channels (Messrs. George Kent, Ltd.). For air in conduits and passages (Messrs. Davis).]

(*e*) Floats. [For measuring the velocity of water in open channels.]

3. Meters which Depend on the Drop of Pressure due to an Obstruction Placed in the Stream.

(*a*) Weirs. [For liquids in open channels (The Lea Recorder Co. Ltd., 28 Deansgate, Manchester, and Messrs. George Kent, Ltd.).]

(*b*) Venturi tubes. [For water, air, steam and gas (Messrs. George Kent, Ltd.).]

(*c*) Nozzles. [For gas (Messrs. George Kent, Ltd.). For steam (The General Electric Co. of Schenectady, and Messrs. George Kent, Ltd.).]

(*d*) Circular, cord, or tongue orifices. [For water, air, gas and steam (Messrs. George Kent, Ltd.).]

(*e*) Variable orifices. [For water, air, gas and steam (Messrs. George Kent, Ltd.).]

---

* See Hodgson, *Proc. Inst. C.E.*, Vol. CCIV, Part 2, and Mavor, *Trans. Inst. Mining Engineers*, Vol. L, Part 4.

ROTARY OR TURBINE METERS.

(*a*) Which measure the whole of the flow passing. [For water (Messrs. Guest & Chrimes Ltd., Rotherham; Messrs. Hayward Tyler, Luton; Messrs. George Kent, Ltd.; the Self Engineering Co., London). For air and gas (The Rotary Meter Co. (1905) Ltd., Victoria Works, Whitefield, Manchester, and Messrs. George Kent, Ltd.).]

(*b*) Which are placed in a shunt circuit. [For air, steam, and gas (Messrs. George Kent, Ltd.).]

5. METERS BASED ON THE MOVEMENT OF A SPRING OR WEIGHT CONTROLLED OBSTRUCTION PLACED IN THE PIPE LINE.

(*a*) In which a disc moves axially in a circular chamber with conical or perforated walls. [For water (The Palatine Engineering Co. Ltd., Bootle, Liverpool). For gas or air (The Rotary Meter Co. (1905) Ltd., Victoria Works, Whitefield, Manchester). For steam (The Drayton Meter Co.).]

(*b*) In which a shaped plug opens up an orifice. [For steam (The St. John Steam Meter Co., New York).]

(*c*) In which a weighted hinged gate is opened by the flow. [For water and air (Messrs. George Kent, Ltd.).]

6. METERS BASED ON THE DROP OF PRESSURE CAUSED BY FRICTIONAL LOSSES IN A LENGTH OF CHANNEL OR PIPE LINE.

[For measuring irrigation water (Messrs. George Kent, Ltd.).]

7. METERS BASED ON THE INTRODUCTION OF A MEASURED AMOUNT OF (*a*) HEAT, OR (*b*) CHEMICAL REAGENT, AND THE CONSEQUENT RISE OF TEMPERATURE OF THE FLUID, OR DILUTION OF THE REAGENT AT SOME POINT FURTHER DOWNSTREAM.

(*a*) The Thomas meter. [For air and gas (Messrs. Humphreys & Glasgow, London).]

(*b*) [A method used for measuring the discharge of rivers and canals, recently further developed for the measurement of air and steam flows. Salt solution is usually introduced when measuring water-discharges, and ammonia or carbon dioxide gas when measuring steam or air flows.]

8. METERS BASED ON INCREASE OF WEIGHT DUE TO CHEMICAL ABSORPTION.

Notes.

Meters of classes 1 (*c*), (*d*) and (*e*) can be made accurate to within plus or minus 1 per cent. from zero flow up to the maximum flow which they are designed to measure. The chief source of error of meters of class 1 (*d*) is variation in the water level, and in meters of classes 1 (*b*) and 1 (*e*) wear of the valves.

Meters of classes 2 (*a*), (*b*) and (*c*) are usually only accurate down to one-third or one-sixth of the maximum flow for which they are designed, as their indication depends upon the square of the velocity of the fluid. Few anemometers are accurate when working at less than one-tenth of their maximum rated capacity.

Meters of classes 3 (*a*), (*b*), (*c*) and (*d*) are usually accurate down to one-fifth or one-tenth of the maximum flow. If specially sensitive differential pressure-measuring devices are provided, such meters may be made accurate down to one-twentieth or one-thirtieth of the maximum flow. By using a variable orifice, the range over which accurate measurement is possible with any given indicator or recorder is greatly extended. These meters have the very real advantage of having in the pipe line no moving parts which can be deranged by dirt or erosion. The Venturi tube, with its smooth contours which eliminate eddying, is a valuable device when measuring dirty gas. Meters of this class show many ingenious arrangements for obtaining an accurate measurement of the differential pressure over a wide range and for compensating for variations in the specific gravities of the fluids or gases to be measured.

Meters of class 4 are not usually accurate in practice below one-tenth of the maximum flow, though many makers claim much higher ranges of accuracy. Endeavours have been made to increase the range of accurate measurement by opening up additional jets at low flows, or by introducing additional resistance at the high flows. While these devices frequently give excellent results under test conditions, they rapidly get out of adjustment under working conditions. Water meters of this class can often carry considerable overloads, thus greatly increasing the range over which accurate measurements may be obtained.

Meters of classes 5 (*a*), (*b*) and (*c*) are capable of high accuracy over a large range of flow when measuring clean fluids. They rapidly lose their accuracy, however, when measuring dirty fluids, owing to the small clearances becoming choked.

The accuracy of meters of class 6 is dependent upon an accurate knowledge of the area of the channel and its resistance coefficient. These are apt to change owing to silting up and the growth of weeds.

In the following pages the main features of some of the best known, or the most noteworthy, meters are described and illustrated.

Water Meters

The Kent Mark III Positive Water Meter.

This meter is shown diagrammatically in fig. 1. Its sequence of operations is as follows:—

1. The piston A descends, and the disc P throws over the valve C.
2. The piston B descends, and the disc R throws over the valve D.
3. The piston A descends, and the disc Q throws over the valve C.
4. The piston B descends, and the disc S throws over the valve E; and so on.

Stops M limit the motion so that an exact quantity of water is measured off each stroke.

Projections K enter the outlet passage at the end of the stroke and prevent jar by slightly throttling the flow.

The cylinders are lined with brass, and the valves and valve faces are made of gun-metal. The valves are caused to oscillate slightly each time they are thrown over in order to keep the rubbing surfaces polished. For the same reason the pistons are caused to rotate a slight amount at each stroke.

The valves are held up against the port block by rollers L carried by springs which press inwards towards the valve faces.

The meter body is jointed along the line XY, which enables all parts to be readily accessible (actually the inlet and outlet flanges are at right angles to the positions shown in the diagram).

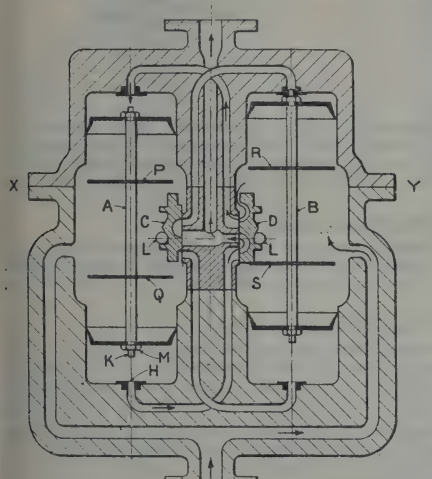

Fig. 1.

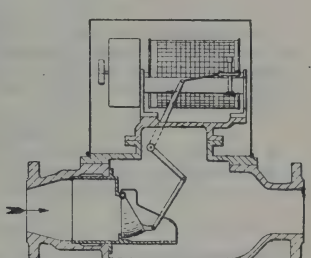

Fig. 2.

The Kent Waste Water Meter.

This meter (fig. 2) consists of a weighted gate pivoted on a horizontal axis and surrounded by a machined shield. The gate opens with increase in the flow, and takes up a definite position at each flow. Its motion is transmitted to the diagram through a stuffing box by means of link mechanism.

It is possible with this meter to measure with accuracy down to very small fractions of the full flow.

Owing to the absence of all sliding parts in this meter, the friction of the mechanism is extremely small.

The bulk of the meter, and the loss of pressure across it, are also reduced to a minimum by its arrangement, which allows of a direct flow between inlet and outlet.

The Beck 'Imperial' Water Meter.

In this meter (figs. 3 and 4) the rotation of the arm A attached to the spindle D, which drives the counter, causes the spherical valve cap V to rock on its seating S, thus opening the lower parts of each of the three cylinders C successively to the inlet and discharge sides of the meter.

The valve cap V is prevented from turning round on its own axis by the projections Q, which engage in recesses left in the valve seat S. The length of the stroke of the pistons is limited by the flange P on the valve cap V, which comes into rolling contact with a machined surface on the valve seat S.

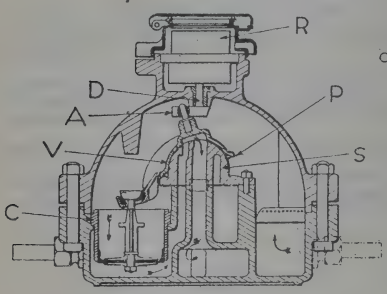

Fig. 3.

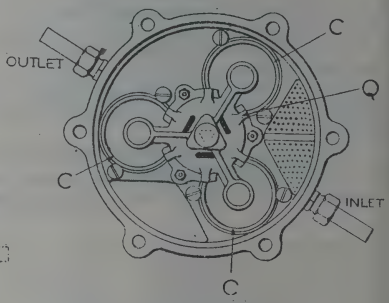

Fig. 4.

It will be seen that the valve cap V moves with a lens-grinding action. This ensures that it and the seating will remain polished and unscratched even when gritty water is being measured.

The valve cap and the pistons are made of hard gun-metal, the valve seat and bushes of vulcanite, and the cylinders of either vulcanite or gun-metal; vulcanite being used for water of exceptional hardness.

The Deacon Water Meter.

In the Deacon Water Meter (fig. 5) a weighted disc moves vertically in a conical shield. Its motion is transmitted to the diagram by means of thin wire passing through a gland. Guide plates are provided to steady the flow at the entrance to the conical shield. See also p. 1482.

The Kent Venturi Water Meter.

This meter (fig. 6) consists of (*a*) a Venturi tube VT through which the water passes; (*b*) a large mercury **U**-tube provided with floats FU and FT (which are displaced by the differential pressure which exists when water is passing between the upstream and throat pressure holes of the Venturi tube); and (*c*) diagram counter and recording mechanisms, which are actuated by the movements of the floats.

The motion of the floats is transmitted to the outside of the **U**-tube by means of gland spindles GU and GT, which actuate toothed wheels that engage with the racks RU and RT.

The law of flow through a Venturi tube is given by the equation :—

where,
$$Q = \frac{\Omega\, a_1}{7{\cdot}88}\left[\frac{h\,W}{n^2-1}\right]^{1/2},$$

Q = flow in lbs. per sec.; Ω = coefficient of discharge for the tube (usually about 0·99); a_1 = area of tube at upstream pressure holes in sq. ins.; na_1 = area of tube at throat pressure holes in sq. ins.; h = difference of pressure between upstream and throat pressure holes in ins. of water; W = weight in lbs. of 1 cub. ft. of the fluid passing.

The counter recording mechanism operates as follows :—A cylindrical cam LC, which has a slightly raised portion, is rotated once every ten minutes by clockwork. A pivoted arm A, which carries the roller L, which is kept in contact with the surface of the cam by a spring (not shown), is lowered by the rack to which it is attached when the flow increases. The greater the distance the arm is lowered, the larger is the fraction of each revolution of the cam during which the roller is on the unraised portion of the cam. By means of mechanism (not shown) it is arranged that a toothed wheel which drives the counter is put into gear with the clock train during the period that the roller L is on the unraised portion of the cam. The boundary line between the raised and the unraised portions of the cam is so shaped that when the pivoted arm A carrying

the roller L moves down a distance H from its zero position an amount proportional to $\sqrt{H}$ is added on to the counter reading. In this way, with suitable gear wheels in the counter train, a counter record of the amount of fluid that has passed is obtained.

Valves U and T are provided so that the upstream and throat pressures may be shut off, and the meter checked by opening the equalising valve E.

Any air that accumulates in the pressure pipes may be blown off through the air vents provided.

To reduce the chance of air getting into the pressure pipes, these should be taken off horizontally, and not at the top, as shown for clearness in the diagram.

These meters will measure accurately down to one-fourteenth of the maximum flow (and special meters of this type down to one-thirtieth of the maximum flow).

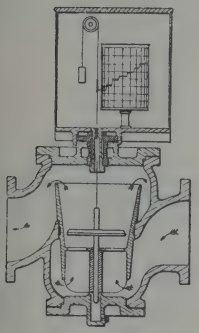

FIG. 5.

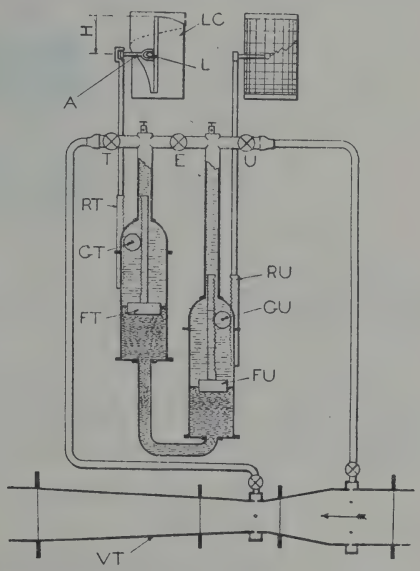

FIG. 6.

The functions of the downstream cone of the Venturi tube is to recover the kinetic energy which exists at the throat, thus enabling the major portion of the pressure difference which has been created between the upstream and throat pressure holes to be recovered.

The friction loss due to the insertion of the water Venturi tube is about 2 lbs. per sq. in. at the maximum flow.

Venturi meters have been used to measure water in all sizes of pipes from about ½ in. to 20 ft. in diameter. They provide the most convenient and accurate method known of measuring the flow of water in large mains. There is a minimum of obstruction to the flow, and there are no moving parts in contact with the flowing water.

Water Weighers.

THE 'AVERY' AUTOMATIC WATER WEIGHER.

The principle of the 'Avery' Automatic Water Weigher (fig. 6A) is that of an equal-armed beam A, with the weights contained in the weight box B, suspended at one end and the weigh hopper C at the other.

A quantity of water, determined by the weights in the weight box B, is allowed to enter the weigh hopper C through the feed valve D.

When the correct amount of water is obtained, the supply from the feed valve or valves D is, by means of a combination of levers, automatically cut off.

Immediately after the supply is cut off, the weigh hooper C automatically tips and discharges its load.

THE 'AVERY' AUTOMATIC WATER WEIGHER—*cont.*

As soon as the contents of the weigh hopper C have been discharged, the weigh hopper automatically returns and assumes the weighing position, at the same time opening the feed valve or valves D, and the cycle of operations is repeated.

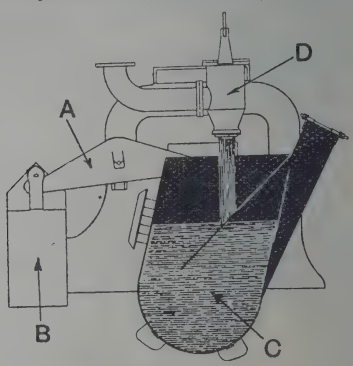

FIG. 6A.

On the large-capacity machines there are two valves at D, the larger one feeding the main flow into the weigh hopper C, then closing, with the result that the final dribble of liquid to complete the weighing and ensure accuracy is fed through the supplementary small valve D.

A mechanical counter keeps an exact record of the number of times the machine operates.

Truck and Hopper Weighers.

THE 'AVERY' PATENT AUTOMATIC WEIGHBRIDGE AND TOTALISER.

This machine, fig. 6B, automatically weighs trucks while at rest on the weighbridge. It also records on special counters the total weights during any period, and the number of weighings made by the machine.

If all the trucks have the same tare weight the machine can be arranged to record the total net weight of material passed over the scale.

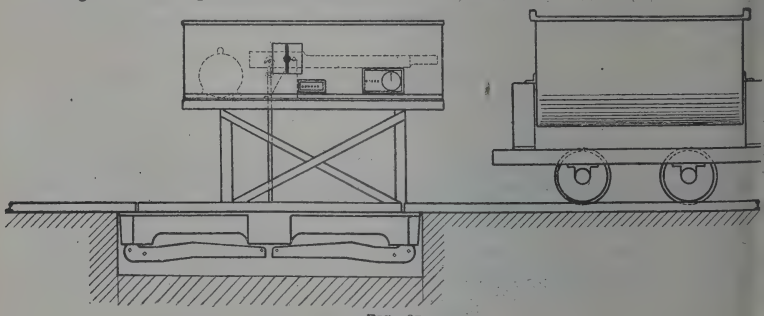

FIG. 6B.

With suitable weighing levers, etc., the machine can be arranged for use with overhead ropeways, grabbing hoists for transporters, overhead runways carrying coke skips for gasworks, etc.

A special type of the mechanism is also used with the Avery 'Automatic Hopper Weighe and Totaliser,' which automatically records the weight of material discharged from grabs o skips. The material dealt with includes coal, coke, ore, pitch, etc., and pieces of any size fron nuts to the largest lumps can be weighed, as there are no feed valves.

When grabs are used to unload barges or steamships this type of machine is most suitable as the total intake of coal is then automatically recorded; also the load of each barge or shi can be ascertained. All the machines described are approved by the Board of Trade as lega weighing instruments, and the recorded weights are therefore beyond dispute.

Weir Recorders.

The Lea 'V' Notch Weir Recorder.

The discharge for a 90° V notch with sharp edges bevelled at 45° on the downstream side is given by the equation.

$$Q = 2{\cdot}48H^{2{\cdot}48}$$

where,

Q = discharge in cub. ft. per sec.; H = head, in ft. above the bottom of the notch.

In the Lea Recorder (fig. 7) the movement of the float F in the weir chamber, which is proportional to H, is transmitted to a cylindrical cam C. By means of this cam, a movement of the pen arm P, which is proportional to Q, is obtained.

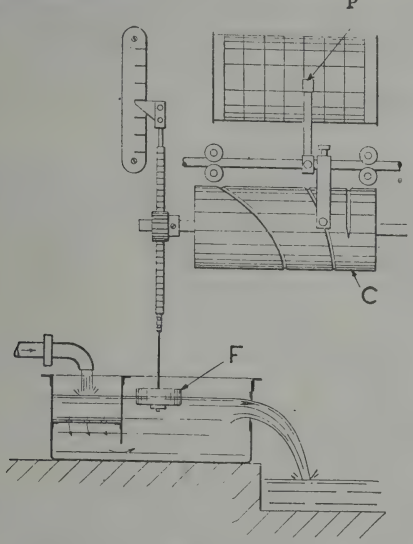

Fig. 7.

These recorders are specially suitable for the measurement of boiler feed-water and condensates, also rivers, streams, reservoir supplies, sewage effluents, etc., or in such cases where it is necessary to measure the water in some form of open channel.

In the Kent Weir Recorder a flat cam is used, and the straight line movements are replaced by movements about fixed pivots.

In the Wright Weir Recorder the weir notch is made of such a shape that the motion of the float is proportional to the quantity passing. In this recorder there is, therefore, no cam between the float and the recorder pen. The approximate shape of the weir notch is shown in fig. 8.

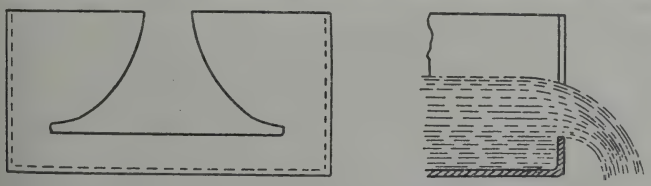

Fig. 8.

Notes on the Use of Orifices, Nozzles, and Venturi Tubes for Test Purposes.

Q = discharge in lbs./secs.;
E = coeff. of discharge;
a_1 = area of main in ins.;
a_2 = area of orifice on throat of nozzle in sq. ins.;
n = a_1/a_2;
N = $a_1\sqrt{n^2-1}$;
d_1 = dia. of main in ins.;
d_2 = dia. of orifice on throat of nozzle in sq. ins.;
h = differential pressure across orifice or nozzle in ins. of water;
p_1 = abs. pressure in lbs./sq. ins. at upstream pressure hole;
p_2 = abs. press. in lbs./sq. ins. at downstream or throat pressure hole;
T_1 = abs. temp. in F.° at upstream pressure hole;
W_1 = specific weight of fluid at upstream pressure hole in lbs./cu. ft. = $2{\cdot}7P_1/T_1$ for air (values for water, steam, and other fluids can be obtained from various published tables);
μ = viscosity of the fluid in foot, pound, sec. units;
γ = ratio of the specific heats if the fluid is gaseous.

The discharge through an orifice, shaped nozzle, or Venturi tube for gaseous or liquid flows can be calculated from the formula:

$$Q = 0{\cdot}127\ EN\sqrt{hW_1}\ \text{lbs./secs.}$$

The value of the coefficient of discharge, E, is the same for the same values of the viscous flow criterion $Q/d_2\mu$, whatever be the density and viscosity of the fluid used, provided that when the fluid which is being metered is a gas, it does not appreciably change in density as it passes through the orifice or nozzle (*i.e.*, p_2/p_1 should be between 1·0 and 0·98).

For shaped nozzles and Venturi tubes, if the numerical value of the viscous flow criterion $Q/d_2\mu$ is greater than 3,000,

$$E = 0{\cdot}94\text{–}1{\cdot}00;$$

for orifices:

$$E = 0{\cdot}605\text{–}0{\cdot}615,$$

provided that:

(*a*) The numerical value of viscous flow criterion $Q/d_2\mu$ is greater than 1,200;
(*b*) d_2/d_1 is not more than 0·6, and that orifices are used which have:
(*c*) square edges if the orifice plate is thin (less than $\frac{3}{10}$th the diameter of the orifice);
(*d*) square edges bevelled off on the downstream side if the orifice plate is thick;
(*e*) pressure holes not more than one pipe diameter upstream, and not more than half a pipe diameter downstream of the orifice.

For the above values to hold, the orifice or nozzle should be installed with at least 6 diameters upstream and 3 diameters downstream of straight parallel pipe free from bends, tees, branch pipes and control cocks.

When using orifices or nozzles for measuring flows of viscous liquids, curves connecting the differential pressure 'h' with the numerical factor multiplying $\sqrt{h/W_1}$ in the volume discharge equation, can be plotted for various values of the kinematic viscosity μ/W.

If the relation between the temperature and the kinematic viscosity for the liquid has been previously determined, a knowledge of the temperature enables the correct numerical factor for any observed head to be read from the plotted curves.

If the flow is gaseous and pulsating, sufficient capacity or throttling must be introduced between the source of pulsation and the metering point to smooth out the pulsation of flow at the metering point, otherwise the meter will read fast. In the case of liquid flows, an air vessel or an open tank may be used.

If gaseous discharge takes place above the critical pressure ratio (*i.e.* if p_2/p_1 is less than $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ when $n=\infty$), the following formulæ hold for shaped nozzles:

$$Q = 0{\cdot}325\ EN\sqrt{p_1W_1}\ \text{for air;}$$

$$= 0{\cdot}316\ EN\sqrt{p_1W_1}\ \text{for steam.}$$

For fuller treatment see Hodgson on 'The Orifice as a Basis of Flow Measurement,' *Proc. I.C.E.*, 1925; 'The Metering of Industrial Fluids,' *Proc. Inst. Mining Eng.*, Nov. 1927.

Gas Meters.

The 'Drum' Type Station Gas Meter.

In this meter (fig. 9) gas enters through the hollow axis in the four compartments of the drum in a pipe which is put just above the water level, and fills each compartment successively, and by its pressure causes the drum to revolve in the direction of the arrow and to register the volume passed on a set of dials.

Meters of this type are used to measure gas in mains of all sizes, from ¼ in. upwards.

Owing to their costliness, the larger meters of this description are now being superseded by new patterns of meter, such as the Thomas and the Kent-Hodgson Meters.

The main sources of error of this meter are deformation or corrosion of the drum, deposition of naphthalene in the drum, and variations in the water level There are various ingenious devices for preventing the meters from being over-filled, and for maintaining the correct water level. If the meter is overloaded, the water level is depressed, and the meter reads slow.

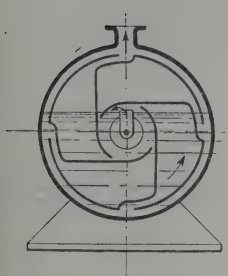

Fig. 9.

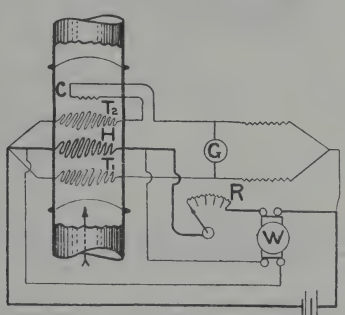

Fig. 10.

The Thomas Gas Meter

In this meter (fig. 10) the gas is passed through a short length of pipe which contains two electrical resistance thermometers T_1 and T_2, which form part of a Wheatstone Bridge. An electrical heater H is placed between the two thermometers. Any increase in the flow of gas causes a lowering of the temperature of the downstream thermometer and a deflection of the needle of the galvanometer G. This is made automatically, by means of a suitable mechanism, to reduce the resistance in the heater circuit, so that the temperature of the gas is always raised the same amount (about 2° F.) by the heater.

The readings on a Wattmeter W, placed in the heater circuit, give the number of cubic feet of gas reduced to standard temperature and pressure.

The Kent-Hodgson Venturi Gas Meter.

In this meter (fig. 11) the 'Venturi Head' $(p_1 - p_2)$ is measured by means of the bell B and an amount proportional to $(p_1 - p_2)$ is added on to the counter reading by means of the cam, feeler, ratchet, and pawl device C.F.R. every time the cam G, which is driven by the wet gas meter W, makes one revolution.

The speed of rotation of this meter is determined by the amount of gas that escapes to atmosphere through a small orifice at O, across which the pressure difference is maintained constant by means of the regulating valve RV.

In this way the counter is made to register the volume of gas passing through the Venturi tube, irrespective of variations in the specific gravity of the gas; the registration of the meter being identical with that of the ordinary Drum type Station Gas Meter.

A diagram, D, is provided which shows the rate of flow of gas at any instant. The readings of this diagram are, however, not corrected for variations in the specific gravity of the gas.

If tar, naphthaline, or other depositable matter settles in the Venturi throat, the meter tends

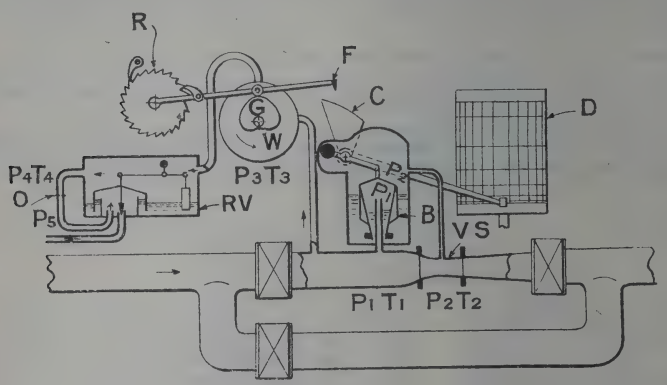

FIG. 11.

to read fast. It is found that when measuring coal gas, such deposits can be entirely prevented by keeping the walls of the throat at a few degrees higher temperature than that of the gas passing through.

The Venturi tube is installed on a bye-pass, and the throat section VS is made so that it can easily be swung out of the pipe line for inspection and cleaning.

The loss of pressure at the maximum flow due to the insertion of the gas Venturi tube is arranged not to exceed 1 in. of water gauge.

The range of accurate registration is down to one-tenth or one-fifteenth of the maximum flow.

If it is desired to reduce the meter readings to standard cubic feet of dry gas, corrections must be made for variations in the barometric pressure, atmospheric temperature, and the tension of aqueous vapour by means of tabular numbers, as is the case with the Drum type Station Meter.

The Venturi Gas Meter is also made in a cheaper form in which the integrating mechanism is driven by clockwork, and any variation in the specific gravity, temperature, and moisture content of the gas is corrected for by means of tabular numbers, *i.e.* the meter readings are multiplied by

$$\frac{(p_1 - p'_1)}{p_1} \sqrt{\frac{W_D}{W_S} \cdot \frac{p_1}{T_1} \cdot \frac{T_S}{P_S}},$$

where,

W_D = weight of a cub. ft. of dry gas at p_1 and T_1; W_S = weight of a cub. ft. of gas containing water vapour at p_1 and T_1; p'_1 = pressure of water vapour at temperature T_1, P_S and T_S the standard temperature and pressure.

See Hodgson, *Proc. Inst. C.E.*, vol. cciv., pp. 164–165.

THE THORP ROTARY GAS METERS.

In the Thorp Rotary Gas Meter (fig. 12), the counter C is actuated by an anemometer fan F, which rotates about a vertical axis.

The gas, after being carefully guided by a series of nozzles N into a vertical direction, impinges on the underside of the blades, thus helping to take the weight of the fan off the bottom pivot. The rate of revolution of the fan is proportional to the actual volume of gas passing

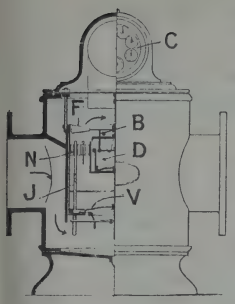

FIG. 12.

except at low flows, when the friction of the mechanism is appreciable. At these flows a weighted valve V (which lifts at the higher flows) causes the whole of the gas to pass through a few jets J, and so to impinge on the fan at an increased velocity. In this way the friction of the mechanism is compensated for, and accurate readings obtained down to one-tenth of the maximum flow.

The dashpot D is provided to steady the motion of the weighted valve. A brake B is attached to this valve, which stops the fan immediately the flow is turned off, as the valve then falls.

This meter registers the actual volume of gas passed, and is subject to the same corrections for variations in the temperature, pressure, and moisture content of the gas as is the ordinary Drum type Station Meter, or the Kent-Hodgson Venturi Gas Meter.

Clogging of the nozzles through which the gas discharges on to the fan causes the meter to read fast. A special form of meter in which the nozzles can be cleaned from the outside, and in which any deposit thrown off from the fan does not accumulate round it, has been devised for measuring dirty gas.

THE 'KENT-HODGSON' ROTARY GAS METER.

This meter (fig. 12A) consists of a body casting inserted in the main, or by preference in a by-pass in the main, a turbine T placed in such a position that gas passing through the two nozzles J on the upstream side of the orifice K impinges on its blades, and a counter mechanism actuated by the turbine. The turbine, orifices, and nozzles can be inspected and cleaned through the hand-holes provided.

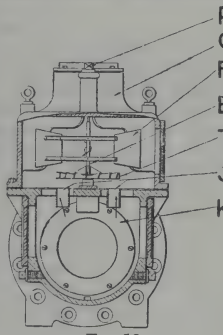

FIG. 12A.

The meter carries the measurement of gas on the rotary principle to the utmost refinement. The speed of rotation of the turbine is kept low by means of the damping fan F, so that wear on the bearings is reduced to a minimum. The weight of the turbine is carried on a mercury float, so that the all-important pivot bearing never wears appreciably, and is also protected by being covered with mercury. The upper thrust bearing and the high-speed wheels of the counter train run in an oil bath. The motion of the turbine is transmitted to the counter dial by means of a magnetic drive similar to that shown in fig. 15, thus eliminating all gland friction and the possibility of moisture depositing on the counter glass.

The turbine chambers and the mechanisms they contain are identical, whatever be the size of the main. The only parts of the meter which vary in size are the body casting which contains the orifice, the orifice itself, and the change wheels which are fitted into the counter train. The length of the body casting in practically all sizes is 24 ins., so that the meter is very light to handle and requires only a short length of pipe line for its installation. It is accurate down to $\frac{1}{10}$th of full flow, and will stand considerable temporary overloads without damage.

HOT WIRE ANEMOMETER.

In this instrument a bare wire with a large temperature coefficient is heated electrically and exposed to the gas flow whose velocity it is required to measure. The velocity V of the gas can then be obtained from the relation

$$I^2 = A\theta + B\theta \left[V.W\,K_p \right]^{\frac{1}{2}}$$

where,

θ = temperature elevation of the wire;
I = current in amps.;
V = velocity of the gas;
W = specific weight of the gas;
K_p = specific heat of the gas at standard pressure;
A & B = constants.

Referring to the diagram (fig. 13), R_1, R_2, and R_3 are resistances with no temperature coefficient, R_4 is the anemometer wire which is maintained at constant temperature when the gas velocity varies by adjusting the resistance R_5 so that the needle of the galvanometer G remains at zero. The current through R_4 is thus proportional to the reading of the high resistance voltmeter V.

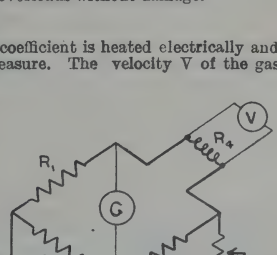

FIG. 13.

The formula given above holds for ordinary gas speeds (9·5 to 30 ft. per second). At speeds below these, free convection currents carry away a considerable proportion of the heat, and the formula requires modification.

The accuracy of the instrument is affected by changes in the temperature of the gas itself, and for this reason it is desirable, when high accuracy is required, to work at a temperature elevation of about 1,000° C. In this case the anemometer wire should be of platinum. For ordinary work a temperature elevation of 200° C. or 300° C. is sufficient, and the anemometer wire may be made of electrolytic nickel.

It will be noticed that the velocity of the gas is approximately proportional to the fourth power of the current. This makes the accurate range of the instrument small, and it also makes it unsuitable for obtaining the mean velocity of fluctuating flows.

In Professor MacGregor Morris's Hot-Wire Anemometer, as made by The Cambridge & Paul Instrument Co., the four arms of the Wheatstone bridge are made of electrolytic nickel.

The wires which compose the two opposite arms of the bridge are shielded from the air current, and the two remaining wires are exposed to it. The instrument is thus automatically compensated for changes in the air temperature, so that it is not necessary for the temperature of the wires to be more than 100° F. above that of the air current to be measured. A constant potential difference is maintained across the bridge, and the air velocity is measured in terms of the out-of-balance current of the galvanometer.

The instrument is calibrated against known velocities in a wind tunnel.

Steam Meters.

The Kent-Hodgson Steam Flow Meter.

This meter (fig. 14) consists of an orifice O placed in the steam main, two cooling chambers CU and CD (whose function it is to condense any steam that passes into them and to serve as reservoirs of water), and pressure pipes PU and PD which transmit the difference of pressure between the upstream and downstream sides of the orifice, due to the steam flow, to the two sides of the differential pressure diaphragms D and to the inside of the pressure diaphragms P.

Any increase of the flow causes an increase of the difference of pressure between the upstream and downstream sides of the orifice, and consequently causes the diaphragms D to contract and

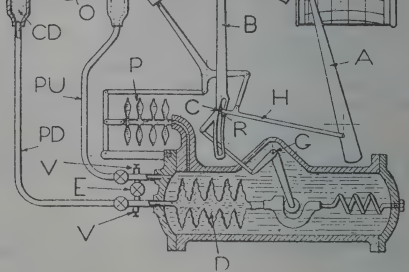

FIG. 14.

the pointer B to move about its pivot C (the motion of the diaphragms D is transmitted to th outside of the diaphragm case through a stuffing box G); while any increase in the pressure o the steam causes the diaphragms P to expand and the arm H to descend.

Air vents V and an equalising valve E are fitted.

The product of the angular movement of the arm B (which is proportional to the differentia pressure $(p_1 - p_2)$ and the travel of the roller R in its slot (which is proportional to the absolut pressure of the steam p_1) is transmitted to the pen arm A, which is thus given a motion pro portional to $(p_1 - p_2)\, p_1$.

Since the rate of discharge of steam through an orifice is represented approximately by the equation,

$$Q = K\sqrt{(p_1 - p_2)p_1},$$

where,

p_1 = absolute pressure of the steam on the upstream side of the orifice; p_2 = absolute pressure of the steam on the downstream side of the orifice; Q = lbs. of steam per hour; K is a constant depending upon the size and proportions of the orifice used.

The diagram can be divided to show the rate of steam flow at any instant, automatically corrected for variations in the pressure. (The corrections for variations in the superheat or wetness of the steam* are made by means of tabular numbers.)

The meters can be arranged to record by counter also if desired.

With any given orifice plate the meter is accurate down to one-fifth of the maximum flow for which the plate is designed to deal. If it is desired to measure over a greater range of flow than this, a new orifice plate must be inserted. Each meter is designed to work in connection with any orifice plate. Each orifice plate is calibrated with actual fluid before leaving the works, and the accuracy obtained in practice with this meter is within plus or minus 1 per cent.

With slight modifications, the meters can be used for the measurement of compressed air.

The Hodgson Rotary Steam Flow Meter.

This meter, which is being manufactured by *Messrs. George Kent, Ltd.*, of London and Luton, as shown in section by fig. 15. A portion of the steam passing through the instrument is diverted by means of an orifice plate through nozzles A, by means of which it is caused to impinge on a turbine. The speed of this turbine is kept low by means of a damping fan C, which rotates in water, resulting in a minimum of wear on the turbine bearings. The retarding torque at any given speed due to this fan is made so great that any variation in the corresponding torque due to the turbine, caused by variations in the density of the steam in which it rotates, can be neglected. The turbine rotates at normal flows with a speed proportional to $Q\sqrt{W}$, where Q is the weight of steam passing per second, and W is the density of the steam in pounds per cubic foot. From this it will be seen that a variation of 2 per cent. in the density of the steam will involve a correction of only 1 per cent. in the flow reading. Besides reducing wear on the pivots, the use of the damping fan increases the range of the meter, since it increases the relative velocity between the impinging steam and the turbine. The counter E is mounted in a compartment below the main, a magnetic drive D from the turbine being employed so that leakage of steam or water into this compartment is impossible. Radiating fins assist in keeping the counter cool. The maximum flow which the meter will measure can be altered by changing the orifice plate B; and by fitting a blank plate in place of this orifice plate, and putting the meter in a bye-pass in a large main into which a suitable orifice plate is inserted directly, the largest mains can be metered at a small cost.

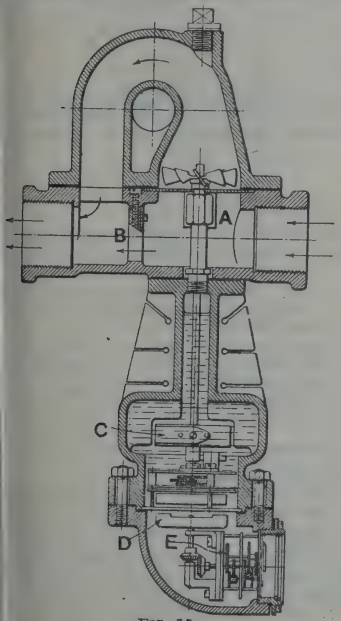

FIG. 15.

The ratio of the revolutions per minute to the rate of flow is constant.

The meters as supplied are accurate down to $\frac{1}{10}$ of the maximum flow, and will stand temporary overloads of 100 per cent. without damage. The meters are also suitable for measuring compressed air.

* About 1 per cent. for every 2 lbs. change in the pressure, or 20° F. change in the superheat, or 2 per cent. change in the wetness.

The Kent-Hodgson Spring-Controlled Flexible Diaphragm Instruments.

The diaphragms in these instruments being required to be sensitive to small differences of pressure, have, with the springs which control them, to be protected from any damage due to overload, or to the application of any considerable unbalanced static pressure, to which they may by mischance be subjected; this, in the Hodgson instrument, is effected by means of a cradle on both sides of the diaphragm. Further, in order that the accuracy of the instrument shall be maintained in use, the diaphragm is reinforced with flexible material which will not stretch radially or circumferentially. The cradle is in the form of a portion of a cone, on which a suitably shaped diaphragm can roll and unroll without stretching. From fig. 16 it will be seen that whatever position along its axis the stiff central plate BC may take up, the length AB is always equal to the length AB_1.

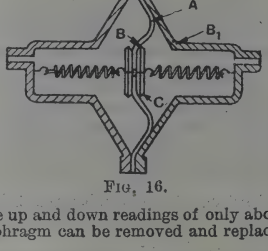

Fig. 16.

In order to obtain a good zero, the controlling springs are under stress when there is no load on the instrument, so that there is no backlash to be taken up when the diaphragm begins to move.

The motion of the centre of the diaphragm is transmitted to the indicating pointer or the recording pen by suitable means (not shown in the figure).

The instruments as constructed show a lag between the up and down readings of only about 1/500th part of the maximum applied pressure. The diaphragm can be removed and replaced without altering the adjustment of the instrument.

The arrangement is more especially suitable for use in connection with the measurement of flow through orifices and Venturi tubes, where small pressure differences at high static pressures have to be measured.

The instruments as supplied are fitted with an 18-in. rate of flow scale, and can be arranged to record by diagram or by diagram and counter.

Coal Meters.

These meters are designed to measure either (*a*) *the total quantity* of coal going to any particular furnace, or (*b*) *the rate* at which the coal is fed. The Avery meter (type *a*) actually *weighs* the coal supplied. The Lea and Kent meters (type *b*) *measure the volume*, i.e. not the weight, of the coal supplied.

The 'Avery' Automatic Coal Weigher.

The principle of the 'Avery' Automatic Coal Weigher (fig. 17) is that of an equal-armed beam A with the weights contained in the weight box B suspended at one end and the weigh hopper C at the other.

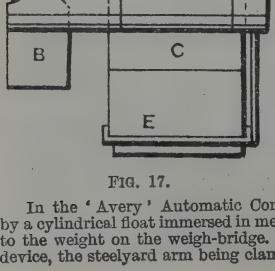

Fig. 17.

A quantity of coal, determined by the weights in the weight box B, is allowed to enter the weigh hopper C through the feed shoot controlled by the valve D.

When the correct amount of coal is obtained, the supply from the feed shoot is, through a combination of levers, automatically cut off by the valve D.

Immediately after the supply is cut off, the door E of the weigh hopper C automatically opens and the load is discharged.

When the load is clear of the weigh hopper door E it closes again and automatically opens the feed valve D, and the cycle of operations is repeated.

A mechanical counter F keeps an exact record of the number of times the machine operates.

Coal or other granular material which is carried by belt conveyors can be weighed to an accuracy of *plus* or *minus* 1 per cent. by supporting a short length of the conveyor on a weigh-bridge and introducing a device which automatically integrates the product of the speed of the conveyor, and the *net* reading of the weigh-bridge.

In the 'Avery' Automatic Conveyor Weigher, the pull on the steelyard arm is balanced by a cylindrical float immersed in mercury, the movement of the arm being thus made proportional to the weight on the weigh-bridge. Integration is effected by means of a feeler and free-wheel device, the steelyard arm being clamped while the feeler is in contact with it.

Lea Coal Meter—Chain Grate Type.

The object of this meter is to measure the amount of coal consumed by a chain grate mechanical stoker.

The coal, as it passes from a hopper underneath a movable fire door, assumes the form of a continuous stream of rectangular cross-section. The volume of coal, therefore, having passed during any given time is the product of the width of the chain grate, the height of coal as it passes under the fire door, and the linear distance travelled by the grate.

Of these three factors two are variable: firstly, the depth of coal passing over the grate (due to the variation in lift of the fire door): secondly, the speed of the grate (or the distance travelled by the grate over a given time). The meter is so constructed as to take both these variables into account in the following manner:—

A specially cut toothed drum, having at one end teeth cut round the whole of its periphery, and a uniformly decreasing number of teeth cut along the whole of its length, is driven by a small driving chain from the grate itself; thus the speed of the drum is proportional to that of the grate, and accordingly proportional to the linear distance travelled by the grate over any given time.

Meshing with this toothed drum is a sliding pinion, which is directly connected to the fire door by means of a steel cable; its position on the toothed drum, and consequently the number of teeth with which it engages, is, therefore, dependent on the amount to which the fire door is raised or lowered. Thus, the rotation of this pinion is dependent on both the grate speed and the fire door lift, and, consequently, this rotation is in a direct proportion to the volume of coal having passed.

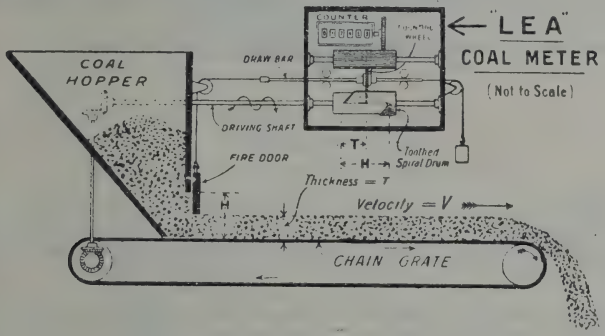

FIG. 18.

The principle of operation of the Lea Coal Meter is as follows:

If W = width of grate in ft.; T = thickness of fire in ft.; V = velocity if grate in ft. per hour; then, cubic ft. per hour = W × T × V = cross-sectional area × V.

The rotation of the pinion is transmitted directly to a row of seven counting dials, the movement of which gives a visible indication of the volume of coal having been fed on to the grate.

It should be pointed out that the meter cannot weigh anything directly; it is solely a measurer of volume, but it eventually determines the nett weight of coal consumed. The Lea Recorder Co., Ltd., guarantees the accuracy of its Coal Meters to be within 2·5 per cent. by volume.

It is quite a simple matter to arrive at the actual weight of coal consumed, by means of tests carried out to determine the average weight of a cubic foot of the particular fuel being used. No variation is caused by the size of the particles of coal, as it is a fact that equal volumes of dry graded coal weigh the same, irrespective of the size of the particles, or whether they are in the form of nuts, peas, or slack.

These Coal Meters can be fitted with patent 'Rate of Flow' Indicator, which, when worked in conjunction with the various speeds of the Stoker drive, gives, on specially graduated scales, the actual amount of coal being consumed at any moment in lbs. per hour.

Lea Coal Meter—Lancashire Type.

In this type of meter the volumetric principle of measurement is adhered to, and the meter is operated directly by the rams, or pusher plates, of stokers of the Proctor, Bennis, and other similar types. The meter is so arranged as to take into account variations of both the speed at which the rams are operated and the differences of travel of the rams, so that a true indication of the amount of fuel fed into the furnaces is given.

The Lea Recorder Company guarantee the meter to be correct within 2·5 per cent by volume.

Lea Cubi-Meter.

The object of this machine, which is a development of the Lea Coal Meter (chain grate type), is to measure bulk supplies of coal, ores, grain, or any other similar granular material, in a continuous manner, in conjunction with elevators or conveyors, on which the material is being handled.

The principle of measurement is volumetric, and is as follows :—

The material to be measured is passed on to an endless belt, in a similar manner to the coal passing on to the grate of a chain grate stoker. The meter itself is similarly driven by a small chain from this belt.

As the material travels over the belt it passes underneath a swinging door, the lift of which varies with the thickness passing under it. Directly connected to this swinging door is a link motion which operates the sliding pinion in the meter. Thus the rotation of the meter dials is proportional to the speed of the belt, and also to the height of the material passing along it, the two factors being combined in the meter giving a true indication of the volume of material having passed through the machine.

These machines are guaranteed to be accurate within 2 per cent. by volume.

Revolution Indicators.

The Jaquet Indicator.

(John Dickinson, 76, Gray's Inn Road, London, W.C. 1.)

This indicator, fig. 19, is an accurate standard instrument which in the shortest time gives positive readings of revolution rate per minute or, using the disc wheel fitted in the case, of linear speed per minute. The standard time unit adopted is 6 seconds, and this unit is controlled by the precision watch movement fitted in the indicator. 1½ seconds are allowed for starting and stopping the watch movement, which also automatically switches the counting mechanism in and out at the start and finish of the 6 second reading unit.

The lever with button which projects from the case winds the watch mechanism ; for each reading one pressure on the button suffices, and the lever is designed not only to wind the watch but also to zero the counting mechanism from the previous reading. This does away with any necessity for resetting the counter after taking a test ; the last reading remains on the dial *until the indicator has been placed in position on the machine* under test and a new reading is required ; then the finger is pressed on the knob and allowed to slide over it so that it can fly back to its full extent, thus resetting the counter and winding the watch.

Either a black or red disc is shown on the face of the counter dial, the colour altering with the direction of rotation and corresponding to that of the set of graduations to be used, black for right-hand, red for left-hand rotation.

One revolution of the large pointer = 1,000 revs. (or 100 m. if the measuring disc is attached) of the small pointer = 10,000 revs. (1,000 m.).

The indicator is designed to stand up to 30,000 revs. per min., and all pivots and bearings are suitable for such high-speed rates.

The indicator is claimed to combine the accuracy of a summating counter with the rapid reading rate usually associated only with tachometers of the centrifugal or magnetic types.

Three fittings are supplied with the instrument: B = rubber point, C = hollow or cup centre, G = measuring disc. The triangular steel point of the spindle can also be used.

The measuring disc G is used for *periphery or rate of cut tests* ; this is fitted with a rubber rim 10 cm. circumference, or if readings are required in feet, the diameter is altered to suit. In cases where shaft centres are inaccessible the revolution rate of same can be determined by using

the measuring disc G and converting the peripheral speed reading to the corresponding revolution rate.

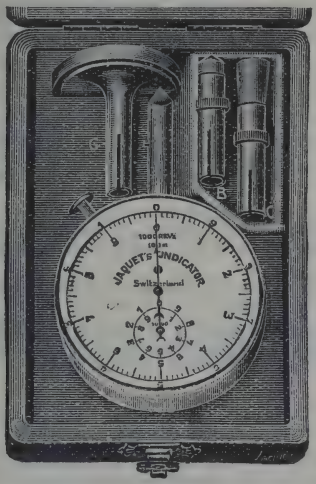

FIG. 19.

An additional model of the foregoing is now made in which 1 rev. of the long pointer = 100 r.p.m.

THE JAQUET HAND TACHOGRAPH.

(*John Dickinson, 76 Gray's Inn Road, W.C. 1.*)

The Jaquet hand tachograph, fig. 20, is used for recording revolution rate, drawing the curve in rectangular co-ordinates on a moving paper strip, marking the time units horizontally and the revolution rate vertically.

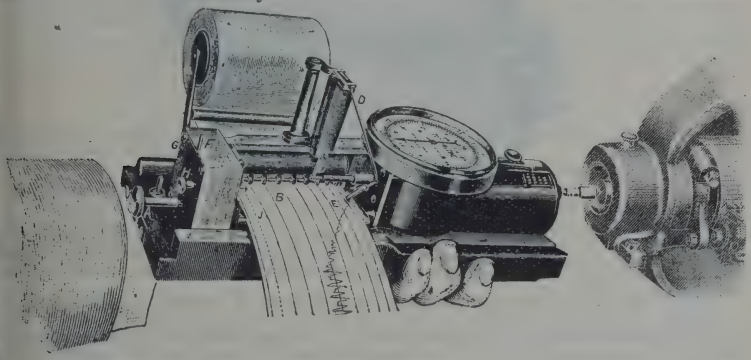

FIG. 20.

It can be used for any desired revolution rate per minute between 30 and 4,000, and allows records of wide speed fluctuations, such as the running-down rate of rotating bodies, and also of such speed rate changes of only 1 to 2 per cent. as occur under governor control.

The mass effect of the recording system is reduced to a minimum, so that records of cycle speed fluctuations are possible.

The record strip is fed forward between two clockwork-driven feed rolls, the clockwork is wound up by the thumb nut A, whilst a trigger at the back (not visible in the fig.) and triggers H and F act respectively to stop or vary the strip feed rate.

Narrow discs are mounted on the top feed roll at positions corresponding to the calibrated revolution rates indicated on the tachometer dial; these discs are in contact with an inking roll C and mark on the record strip parallel lines spaced to agree with the calibration of the instrument.

After a test the r.p.m. value of the inked-in parallel lines can be written in on the record.

The revolution rate during test is taken from the tachometer dial. The thumb nut H winds the watchwork actuating the time recorder J, which marks the record at definite intervals of 1 or $\frac{1}{5}$ second as selected. Usually the apparatus are provided with 1 second registering time markers.

Record of the revolution rate is effected by the pen E, connected through a system of levers D to a spindle projecting from the tachometer and working at right angles to the line of strip advance. Suitable recording ink, which is supplied with the instrument, is put into the pen by a small brush.

An additional fitting may be had, by the use of which the chart spacing may be increased or multiplied, at a small extra charge.

Optical accessories are also available in the way of a flexible drive attachment, whereby readings may be taken from inconvenient positions to allow for easy reading; a neat reducing and multiplying gear-box is also available, at a nominal cost.

The Veeder Magnetic Counters.

(*F. E. Dickinson, St. Andrew's House, Holborn Circus, London, E.C.* 1.)

The 'Veeder Magnetic Counters' differ from the general run of Veeder counting mechanisms in that they operate by the making and breaking of an electric circuit. Their uses are many and varied. They can be placed at a distance from the machine or apparatus the operations of which it is desired to keep account, and they are useful where the articles to be counted are small, or thin, or light in weight, making it difficult to count by mechanical means. No extra contact device need be provided where the counter is to be used in conjunction with other devices already

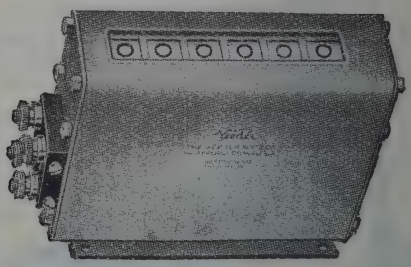

Fig. 21.

electrically operated, and where it is desired to know the number of times these devices are started or stopped. In other cases it is necessary to provide some mechanical device which will close and break the electrical circuit which operates the counter. The counters are made for either direct or alternating current.

Mechanically operated Veeder Counters are used for counting, measuring, and particularly in recording output of many varied products often at different stages of manufacture.

The counter shown by fig. 21 is the larger of the two magnetic devices and is furnished with or without a reset attachment (for the purpose of resetting the counter to zero at any particular point).

SECTION XXVII.

PART II.

MECHANICAL TESTING OF MATERIALS.

(*W. & T. Avery, Ltd., Soho Foundry, Birmingham.*)

As the practice of mechanical testing is essentially a weighing operation, care should be taken by users to see that the machine employed for any testing operation, in which accuracy of results is of vital importance, is one in which the load indications are derived through the medium of weighing levers of the type adopted in good weighing machine practice.

Chains and Anchors.

High-capacity machines of the horizontal type are used for testing such materials. The chain specimen is usually laid in a trough in the flooor, and during the test is covered by steel plates to prevent injury to the operator. A bay in the trough is provided for accommodating anchors when these are required to be tested.

Wire and Hemp Ropes.

Similar horizontal machines to that described above are also used for testing ropes, and the type of grip holder has to be of special design for securing the specimen. Conical extensions are formed on the ends of the wire rope, and in the case of hemp ropes these are secured in holders of the drum type, or sometimes between wood-lined wedges.

Bar Specimens of Steel and Non-Ferrous Metals.

For such specimens a vertical type of testing machine is usually employed, and this may be of the multiple-lever pattern or of the single-lever type.

The straining medium can be either hydraulic power or the load may be applied by means of an electric motor driving suitable gearing. For small machines a hand drive is sometimes used.

Cement and Concrete.*

Cement is tested both in tension and compression, although concrete is usually tested for its compressive strength only.

The machine for the tensile test is generally of the type in which the load is applied gradually through the medium of a flow of shot.

The compression-testing machine used is generally of the hydraulic type, in which the applied load is indicated by a pressure gauge.

Textile Materials and Leather Belting.

Such materials are tested in machines in which the stress is applied at a constant rate of loading.

Usually the machine is of the vertical type, but for very long specimens horizontal machines are sometimes adopted.

The form of grip holder has to be of a special design to obviate the danger of the specimen breaking in the grips.

* See also p. 504.

TIMBER.

The testing of the strength of constructional and aircraft timber has received great prominence during the last year or two. Various tests are adopted, and special speed rates of load application are specified for each.

TESTING APPLIANCES.

Figs. 1, 2, 3, and 4 show various testing appliances.

(Author of 'Dock Engineering,' 'Harbour Engineering,' etc.)

HARBOURS AND BREAKWATERS

Harbours are sheltered areas of water affording safe anchorage for ships generally also provided with quays and facilities for landing passengers and cargo. There are many harbours where the requisite shelter is forthcoming naturally from the physical configuration of the coast line (Queenstown, Rio de Janeiro, etc.). Where protection cannot be obtained in this way it has to be provided by means of breakwaters, as at Portland, Dover, and elsewhere.

Breakwaters are of two types: (*a*) the mound of rubble stone, and (*b*) the upright wall of masonry or concrete. Frequently the types are combined. Sometimes the mound predominates

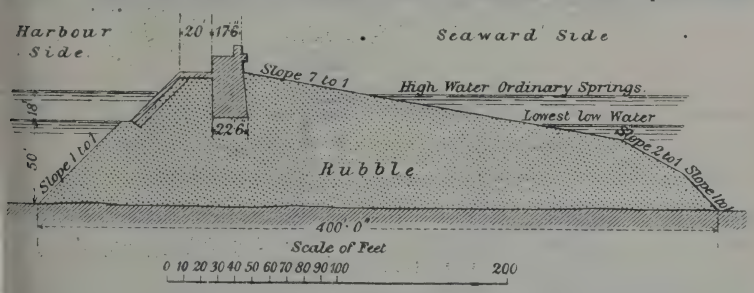

FIG. 1.—Holyhead Breakwater.

and is simply capped by a slight superstructure of regular masonry, as at Algiers and Oran; in other cases it is reduced to a minimum, becoming a mere foundation layer for a wall of massive proportions, as at Ymuiden and Zeebrugge.

The relative advantages of the mound and the wall are as follows:—

1. As regards *efficiency*, the mound is not so serviceable as the wall. The undulations of the sea are transmitted through the interstices of a mass of rubble, and the harbourage area is kept more or less in a state of agitation.

2. As regards *initial cost*, the mound can be formed by unskilled labour, and where that is plentiful and stone abundant, this type of breakwater will commend itself on account of the facility with which it can be constructed. In the absence of these essential conditions, and provided the depth of water be moderate and the foundation sufficiently firm, the wall, involving much less quantity of material, will be found preferable. Especially will this be the case where skilled labour is readily procurable at reasonable rates. Even the difficulty of a defective foundation may be overcome by one or other of several expedients without perceptibly altering the relative positions. But where the sea bottom lies at a considerable depth (40 feet or more) the superior economy of the pure wall cannot be maintained.

CONSTRUCTIONAL COST OF BREAKWATERS.*

Harbour.	Type.	Mean Depth of Water.	Cost per lin. ft.	Remarks.
		Ft.	£	
Alderney .	Composite	90	259	Mound terminates 12 ft. to 15 ft. below L.W.
Algiers. .	Mound	50	122	Large random concrete blocks surrounding rubble.
Dover . .	Wall	40	415	Concrete blocks weighing 26 to 40 tons.
Holyhead .	Composite	54	162	Mound very predominant.
Marseilles .	Mound	35	87	
Bizerta .	Composite	58	60	Wall built on caisson system.
Portland .	Mound	44	127	
Naples . .	Composite	93	186	
Valparaiso .	Composite	60 to 150	560	Concrete monoliths on rubble mound.

An interesting comparison of the estimated (pre-war) cost of four different types of breakwater, based on the conditions at Zeebrugge, Belgium, is made by MM. Bonnet and Braeckman in a paper to the Fourteenth International Congress of Navigation. The depth of the sea bed at Zeebrugge is 26 ft. 3 ins. below zero datum, and the tide rises 15 ft. above zero, giving a total depth of 41 ft. 3 ins. of water. The unit costs per lineal metre (3·28 ft.) are given as follows :—

	Francs.
(*a*) Solid wall of the Zeebrugge type. Total height 66 ft., mean thickness 23 ft.	6,760
(*b*) Composite breakwater with mound of unassorted rubble, the slopes being lightly covered by large natural blocks of 10 cwts. to 6 tons; wall superstructure 33 ft. high	7,600
(*c*) Composite breakwater, mound having core of unassorted rubble, larger material on slopes protected on outer side by artificial blocks of 33 tons deposited haphazard	8,700
(*d*) Composite breakwater with base as before, but with slopes protected by artificial blocks of 31 tons laid symmetrically to inclination	9,000

3. As regards the cost of *maintenance*, this is generally greater in the case of mounds than in the case of walls. A wall, provided it be properly constructed in the first instance, calls for no further attention, save for such rare and occasional damage as results from some storm of

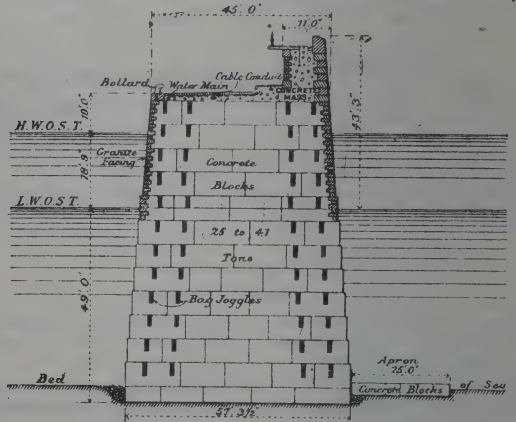

FIG. 2.—Admiralty Pier Extension, Dover.

exceptional severity. The rubble mound, on the other hand, is peculiarly susceptible to wave action, and needs constant replenishment. The cost of this varies very considerably according to situation and exposure. At Holyhead it was for many years as low as 1*s.* 3*d.* per lin. ft. per annum, but latterly there has been some extensive replenishment at considerable outlay; at Genoa, the

* The impossibility of accurately adjusting costs and prices, where they are quoted, to the altered and variable conditions arising out of the war has rendered it advisable to retain them on their old pre-war basis, leaving the necessary adjustments to be made as occasion may require.

cost is stated to be 7*s.*; at Naples, 13*s.*; while at Alderney, during a certain period, it rose as high as 45*s.* This last, however, is quite an abnormal figure, and under ordinary conditions the pre-war annual expenditure on mounds of suitable design hardly exceeded a pound a foot.

Wave Action.

Wave Action.— Wave action on breakwaters is most keenly marked between the levels of high and low water, but it extends to a depth of 30 ft., and there are instances on record of serious disturbances at even greater depths. Thus, at Peterhead, blocks weighing upwards of 41 tons have been displaced at 36½ ft. below L.W.O.S.T. But cases of this kind are exceptional. Generally speaking, at a depth of 5 fathoms the sea is fairly quiescent and a rubble mound may be counted upon to stand therein with side slopes of from 45° to 50°.

Above this level much flatter slopes become necessary : 2, 3, 4, 5, and even 7 to 1. Unfortunately, while the equilibrium of the mound demands such gradual inclinations, they serve also to foster the disruptive action of waves, which, passing up a long seaward incline, have their oscillatory character changed into one of translation. At the summit the impact delivered is so powerful as to produce a pressure which Stevenson records as being six times as great as that against a steep wall. This inimical effect can only be counteracted by the use of huge blocks and monoliths, covering the exposed surface of the mound. The blocks, which in practice rarely weigh less than 25 or 30 tons apiece, and often considerably more, may be deposited either in courses or at random. In the former case they are generally stepped so as to conform to the general inclination. In either arrangement they should be laid as headers, pointing seaward, so as to expose the least extent of surface to wave-action and at the same time gain the utmost

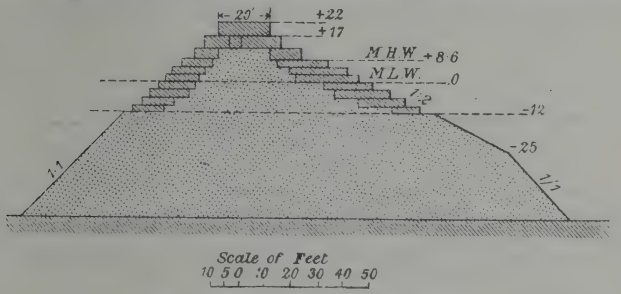

FIG. 3.—Sandy Bay (U.S.A.) Breakwater.

advantage from the moment of resistance to overturning. Hence prisms or parallelopipeds are decidedly preferable to cubes.

The *maximum pressure* exerted by waves does not appear to exceed 3½ tons per sq. ft. At Skerryvore, on the Atlantic, a pressure of from 2½ to 2⅝ tons per sq. ft. has been observed; at Bell Rock, in the North Sea, 1½ ton; at Dunbar (East Lothian) 3½ tons, and at Buckie (Banffshire) 3 tons.

Composite breakwaters, in which the wall plays any important part at all, should be so designed that the *back draught* or *after-tow* of the waves cannot undermine the superstructure. To be really effective, this means that the wall should be carried down to a depth of at least 30 ft. below low water, and though in the past many such walls have been founded at low water level, or very slightly below it, yet the experience gained has proved that this depth is quite inadequate (the low water zone is particularly dangerous), so that of late years there has been a continual tendency towards increasing the depth of the foundation level. At Bilbao the wall commences at 16½ ft. below low water; at Madras 27½ ft.; at Naples 33 ft.; and at Peterhead 43 ft.

Methods of Construction.

Methods of Construction.—Breakwaters are constructed in several ways, according to situation and type.

For **Mound Breakwaters**, rubble may be deposited—(*a*) from barges or scows; (*b*) by means of cranes running on temporary staging; and (*c*) from wagons passing over roads laid at or about the level of the top of the mound and extended as the work proceeds.

The first method is best adapted to sheltered situations, and affords an opportunity of depositing rubble uniformly and simultaneously over the whole site, but it is not practicable to carry on operations in this way at or about surface water level nor above it. Moreover, the progress of the work is very dependent on weather conditions, and there may be long periods of enforced inaction. It is to be noted in passing that irregular deposits of rubble lead to current action and scour. The second method (staging) admits of operations being carried on uniformly over the site, though not with quite the same degree of freedom as in the case of barges. But the advantages of a stable working base with infrequent interruptions and higher degree of safety and

protection for workers, are very pronounced. The damage sustained by timber staging in storms and from the attacks of marine borers are drawbacks which detract from the merits of the system, though, generally speaking, the former is proportionately not a serious matter, and any

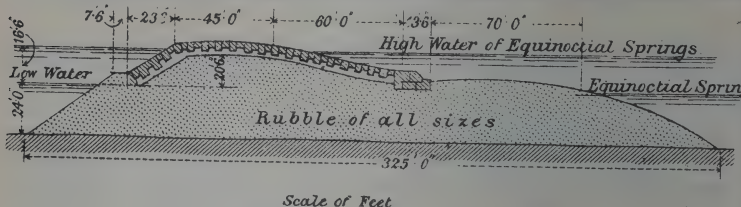

FIG. 4.—Plymouth Breakwater.

evil results of the latter can be to some extent guarded against by careful inspection. The third, or low-level system of construction, by means of tipping from wagons running on tracks laid on the breakwater itself, assists in the consolidation of the work as it proceeds, and saves the cost

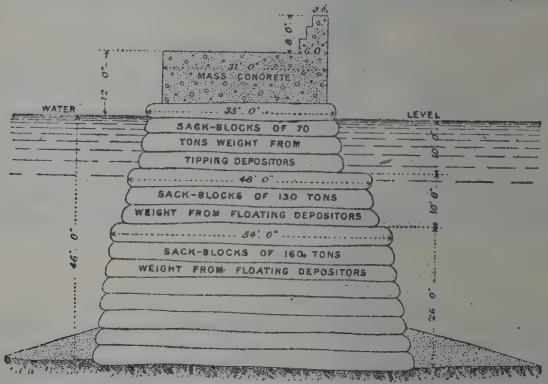

FIG. 5.—La Guayra Breakwater.

of staging, but the area of operation is limited and there is liability to interruption during the prevalence of heavy seas. It is a method more adapted to small embankments, where time also is perhaps not a matter of prime importance.

Wall-Breakwaters.

Walls are constructed either by means of staging, or on the low-level, end-on system: the former being generally more suitable when concrete is deposited in mass, and the latter for blockwork. The blocks, or monoliths, are deposited in place by huge revolving cranes, known as Titans, and overhead travellers known as Goliaths (p. 907). A modern Titan is a powerful cantilever crane capable of dealing with blocks of from 30 to 60 tons weight, at a working radius of as much as 100 ft. A 41-ton steam Titan used on the breakwater at South Shields had a radius of 75 ft., and was carried on 16 central-flanged wheels running on rails set to a 22 ft. gauge. The speeds of the various motions were as follows: Lifting full load, 6 ft. per min.; lifting loads up to 10 tons, 25 ft. per min.; racking full load, 20 ft. per min.; racking loads up to 10 tons, 50 ft. per min.; slewing, one revolution in 4 min. Goliaths are constructed to the same lifting capacity as Titans, and some command a lateral range of travel of 100 ft. or more, but the span is generally limited to about 50 or 60 ft. At Dover, a 42-ton steam Goliath had a range of 130 ft., a clear headway of 25 ft., and a total lift of 120 ft. The speeds of movements were: Lifting, 10 ft. per min.: crab travel, 50 ft. per min.; and main travel, 60 ft. per min.

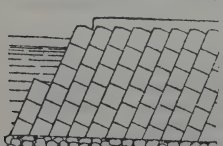

FIG. 6.—Sloping Bond.

Special Methods of Construction.

Special methods of breakwater construction include the use of bags, or sacks, of concrete, weighing from 50 to 200 tons, for deposition under water by divers, as at La Guayra; large caissons, or tanks, of reinforced concrete, with volumes of 60,000 to 70,000 cu. ft., floated out into position, sunk and filled in solid, as at Bizerta; and blocks set on end, slightly tilted (15° to 20°) out of the vertical, so as to form what is called *sloping bond*, the object being to allow for unequal settlement in the foundation. Small breakwaters in shallow waters are sometimes constructed of cribwork—box-shaped frames of timber in openwork with cross partitioning and ties, weighted when in position with rubble—but the system is not very durable and only suitable for comparatively sheltered situations.

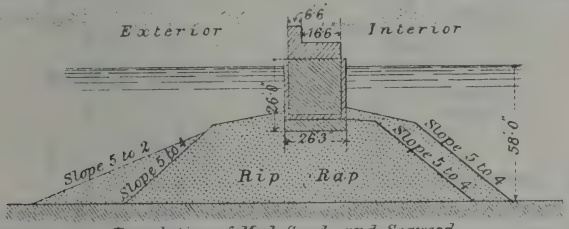

FIG. 7.—Bizerta Breakwater.

DOCKS.

Docks are enclosed repositories for shipping. Where the enclosure is not complete and there is free communication with the sea, the term *Basin*, though not universally employed, is more appropriate. Docks proper are fitted with gates or caissons, either in order to impound the water at a fairly constant level, in which case they are distinguished as *wet docks*, or to exclude the water, in which case they are known as *dry* or *graving docks*. *Floating Docks* are movable structures capable of lifting vessels out of the water and supporting them by their own displacement.

CONSTRUCTIONAL COST OF WET DOCKS.*

(Note: The variety and range of design and equipment render any very effective comparison out of the question.)

	Per acre of Water Surface.		Per acre of Water Surface.
Alexandra Dock, Hull	£28,900	Barry Docks	£12,950
Alexandra Dock, Liverpool	23,300	Prince of Wales Dock, Swansea	18,600
Avonmouth Dock, Bristol	22,600	Queen's Dock, Glasgow	24,450

KING GEORGE V. DOCK, LONDON.

One of the most notable docks constructed in recent years is the King George V. Dock at London, which adds 64 acres to the enclosed water area of the port. The dock has a depth of 38 ft., and the quayage aggregates approximately 10,000 ft. A section of the north, west, and east quay walls is given in fig. 11. An unusual feature on the south side of the dock, shown in fig. 12, is the provision of seven reinforced concrete jetties, each 520 ft. long and 22 ft. wide, which have been constructed at a distance of 32 ft. from the face of the main quay wall, the only shore connection being a timber foot-bridge. The arrangement is due to the fact that a preponderating portion of the goods arriving at the port is transferred to barges for conveyance to their ultimate destination up river. Ships are berthed on the outside of the jetties, and the jetty cranes can discharge goods therefrom either on to the quay for delivery to carts or railway trucks, or for sorting or temporary storage at the sheds behind, or, alternatively, into barges lying in the space between the jetties and the wall.

The entrance lock from the river Thames is 800 ft. long by 100 ft. wide, with a depth of water on the sill of 45 ft. below Trinity high water. The chamber is divided into two compartments, of 550 ft. and 250 ft. respectively, by three pairs of steel lock gates, each leaf of which weighs 309 tons. By the use of a floating caisson, for which provision has been made at the inner end of the lock, the available length can be increased to 910 ft. The cost of the dock with its equipment was about £4,130,000.

* See footnote, page 1520.

The Gladstone Docks, Liverpool.

Another notable example of recent dock construction is the Gladstone Dock System of the Mersey Docks and Harbour Board, opened to traffic in 1927. It consists of a vestibule, or turning, basin with two branch docks, the whole comprising a water area of 58¼ acres. The vestibule dock is entered from the River Mersey by a lock of outstanding dimensions. It is 1,070 ft. in length and 130 ft. in width, divided into two compartments, with sills 20 ft. below Bay Datum, giving 48 ft. 4 ins. depth of water at H.W.O.S.T., 35 ft. at half tide level, and 22 ft. at L.W.O.S.T. Both the branch docks are 400 ft. wide; one is 1,420 ft., and the other 1,285 ft. long. They are equipped with treble storey sheds of reinforced concrete construction, providing floor areas (including the flat roofs which are designed for light loading) of 32 acres and 23 acres respectively. The system includes a graving dock which is the largest in Europe. The length of the dock from the head to the inner caisson sill is 1,050 ft. 4 ins. The width of entrance is 120 ft. and there is a depth of water over sill of 43 ft. 6 ins. at H.W.O.S.T. This dock has the peculiarity that it can be used as a wet dock, and for that purpose it is equipped with a single storey shed on its north side.

Dock Walls.

Dock Walls.—Under present-day conditions it is necessary for quay walls to possess a perpendicular, or almost perpendicular, face. Ships are now built to a square, box-like section amidships, with vertical sides inclining inwards towards the top. Unless, therefore, there is an absence of batter in the walls, vessels will be unable to lie as closely in contact with the quay coping as is desirable, and quay cranes for loading and discharging them will have to be provided with a greater outreach than is absolutely necessary, at an enhanced cost.

Dock walls are constructed of masonry, brickwork and concrete—nowadays generally the latter, deposited in mass with sometimes a brick or stone facing. There is nearly always a coping course of granite. A toe in front of the wall adds to its stability and prevents any undermining of the foundation. The material forming the backing should be carefully selected so as to admit of proper drainage, and weep or vent holes should be provided in the wall at intervals of 50 feet or so, to admit of water escaping through to the front when the level of the dock is lowered in any way.

The composition of *Concrete* for the hearting of dock walls may safely be put at 8 parts of aggregate by volume to 1 part of sound Portland cement. Of the aggregate the sand while not exceeding 3 times the cement will at least suffice to fill the interstices in the gravel. Stone rubble plums can be used to advantage, provided they are completely bedded in concrete and do not come within 6 inches of each other or the face. The facing of the wall, if of concrete, will be composed of equal parts of gravel, sand and cement.

The *essential features of a quay wall* are weight and resistance to slip. The first is secured by using heavy material and providing ample sectional area; the second by giving a suitable bevel to the surface of the foundation so that it slopes downward from the front of the wall to the back, at the same time taking care that the maximum intensity of pressure does not exceed a certain limit, which, in the case of stiff clay, is 3 tons per sq. ft.; in the case of unconfined sand and gravel, is 2 tons; and in the case of soft, uncertain ground, is 10 cwts. per sq. ft.

Stresses in Dock Walls.

Stresses in Dock Walls.—The calculation of the stresses in a dock wall is a very complex problem, involving a considerable number of elements, the exact determination of which is impracticable, so that they have largely to be based on conjecture. Briefly stated, the conditions are as follows: The wall is subjected to the overturning influence of a wedge-shaped mass of earth which represents the excess of material behind the wall lying above the plane of natural slope of the material. The pressure, of course, is intensified by any surcharge upon the surface area of the wedge. The restraining force is the weight of the wall itself, acting vertically downward, assisted to some extent by the earth backing which may rest upon offsets, if any, at the back of the wall.

In fig. 13, let A B D K G be the outline section of a dock wall.

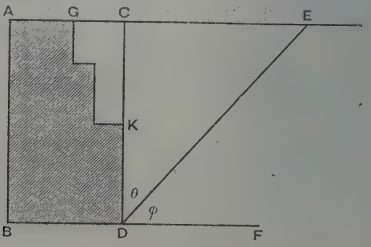

FIG. 13.

Let E D be the plane of natural slope of the ground behind the wall, i.e., the slope which the material would assume if left unsupported. The angle E D F will be designated ϕ and is known as the Angle of Repose.

Let the height of the wall A B be h, and w be the weight per unit volume: and let v be the weight per unit volume of the earth behind the wall.

Then the weight of the wedge of earth behind the wall, tending to overturn it, is

$$\frac{vh^2}{2} \cdot \tan \rho.$$

In order to cover cases where the back of the wall is not vertical and where the surface of the ground is not horizontal, this expression may be written in general terms:

$$\frac{vh^2}{2} \times \text{constant},$$

and the value of the constant, as determined by Professor Rankine in accordance with a theory which neglects any cohesion between the earth particles, is

$$\frac{1 - \sin \phi}{1 + \sin \phi}.$$

The line of action of the overturning force,

$$\frac{vh^2}{2} \cdot \frac{1 - \sin \phi}{1 + \sin \phi},$$

is taken as parallel to the surface of the ground and the point of application at one-third the height of the wall measured from the base.

For simple practical calculations for dock walls where the quay surface is almost invariably

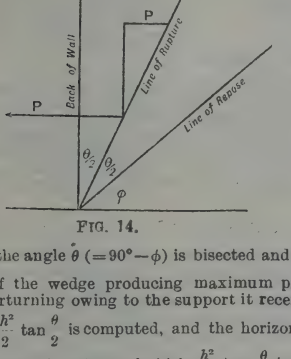

FIG. 14.

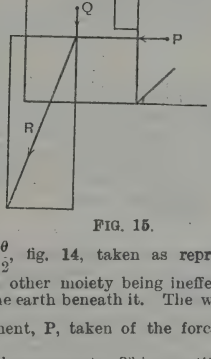

FIG. 15.

horizontal, the angle θ $(=90° - \phi)$ is bisected and the value $\frac{\theta}{2}$, fig. 14, taken as representing the angle of the wedge producing maximum pressure, the other moiety being ineffective as regards overturning owing to the support it receives from the earth beneath it. The weight of the triangle $\frac{h^2}{2} \tan \frac{\theta}{2}$ is computed, and the horizontal component, P, taken of the force acting down the plane of rupture; of which $v\frac{h^2}{2} \tan \frac{\theta}{2}$ is the vertical component. This constitutes the overturning force, which may accordingly be written:

$$P = \frac{vh^2}{2} \tan^2 \frac{\theta}{2}$$

The point of application of P is again at one-third of the height of the wall.

The restraining force Q is measured by the sectional area of the wall A B D G, fig. 13, multiplied by w, together with the sectional area of the earth G K C resting on the wall, multiplied by v, the two acting vertically downwards through their common centre of gravity.

Calling the overturning force P, and the restraining force Q, fig. 15, and completing the parallelogram of forces, the resultant R will be obtained, representing in magnitude and direction the force acting at the base of the wall.

So long as the line of action of R falls within the base of the wall, there is theoretical stability, but, for practical constructional purposes, it is essential:

(1) That the line of action of R should not fall outside the middle third of the base line, and

(2) That the magnitude of R should not be sufficient to crush the base; in which connection it is to be noted that the intensity of pressure increases with the eccentricity of the resultant

(i.e. its distance from the centre) and that when R passes through the limiting point of the middle third of the base, the intensity of pressure on the outer edge is just twice the mean intensity. As a rough practical rule in designing dock walls, the mean width or thickness may be made about one-third of the height. It should never be less than one-fourth. The base width may be about one-half the height, but need never be more than two-thirds.

Entrance Locks.

Entrance Locks.—During periods when the water in a dock is impounded at a higher level than that of the external water (in some cases continuously), the dock can only be entered through the medium of a lock. The size of lock chambers is governed by the dimensions of the ships making use of them, and these vary at different ports. The largest vessels in existence at the present time are 900 ft. to 950 ft. long by 95 ft. to 100 ft. broad, and they draw from 35 ft. to 40 ft. of water when loaded to their full capacity. No port can claim to be of the first rank which does not receive vessels from 500 to 600 ft. long, with 60 to 70 ft. beam and drawing 30 ft. of water.

Dock Gates.

Dock Gates.—Where the rise and fall of the tide does not exceed about 12 ft. the inducement to provide completely enclosed areas for shipping is not great, but above that limit the necessity for impounding the dock water becomes evident on account of the inconvenience arising from rapid changes of level, frequent alteration in moorings, and chafing against the quayside.

Dock gates are either of steel or wood—in the latter case of greenheart, jarrah, or other hard, heavy, durable timber. Greenheart gates cost more than steel gates—in some cases nearly 50 per cent. more—but their natural durability is very great and the cost of maintenance practically nil. Unfortunately, they are subject to the attacks of sea vermin, and in certain ports considerable trouble has been experienced from this cause. Salt water, especially if contaminated in any way with sewage, is extremely deleterious to ironwork, and the life of a steel gate, under these circumstances, can scarcely be expected to exceed 30 years. Greenheart gates have been found in excellent condition at the end of 50 years.

Stresses in Dock Gates.

Stresses in Dock Gates.—Dock (double-leaf) gates are maintained in equilibrium under the action of four external forces:—(1) the resultant pressure of the water against the back of the gate $= \frac{wh^2}{2}$ per lineal foot of gate, where w (62½ lbs. for fresh, 64 lbs. for salt water) is the weight of a cubic foot of water, and h its height behind the gate. This force acts horizontally at one-third of the height. When there is water on both faces $p = \frac{w}{2}(h^2 - h_1^2)$, and the line of action is

* See footnote, page 1520.

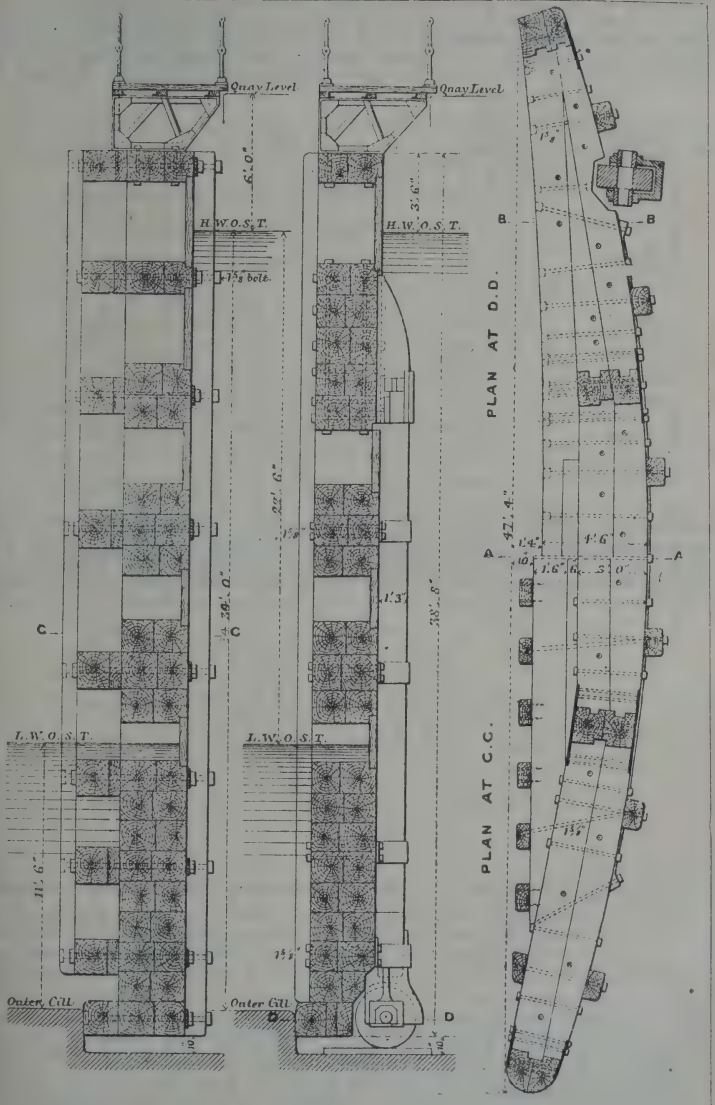

FIG. 16.—Dock Gates. (Timber.)

determined by the centre of gravity of a quadrilateral representing the difference in pressure (2) The reaction of the mitre or meeting posts of the gates acting perpendicularly to the meeting faces, and therefore also perpendicular to the centre line of the waterway. (3) The reaction of the hollow quoins passing through the heel-post of the gate and also through the point of intersection of the other two forces. (4) The reaction of the sill, which is generally neglected.

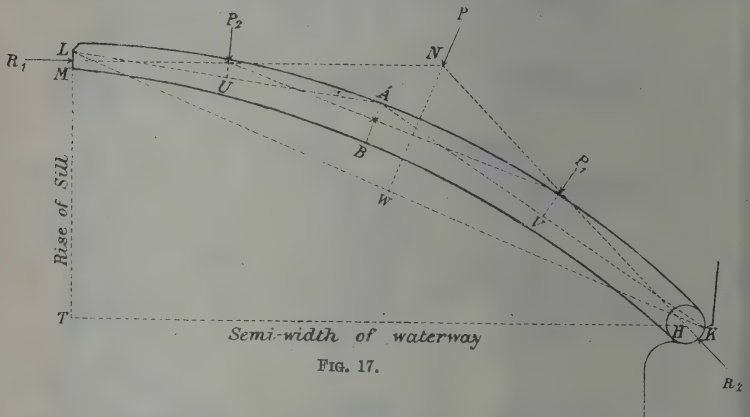

FIG. 17.

Fig. 17 represents the plan of one leaf of a pair of gates. P is the total water pressure upon the back of the leaf, assumed concentrated at its centre. R_1 is the mitre-post reaction of the adjoining leaf, taken as passing through the centre line of the abutting surfaces. R_2 is the reaction of the hollow quoin, assumed to act through the axis of the heelpost. These three forces being in equilibrium, the triangle of forces *ors* (fig. 18) can be drawn, having its sides parallel to

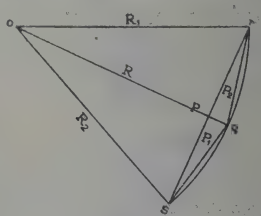

FIG. 18.

the forces P, R_1, and R_2 respectively, and since the magnitude of P is known, the magnitudes of the other two are determined.

If now it be required to find the position and amount of the resultant stress across any section AB (fig. 17) of the gate, the procedure is as follows :—Join the point A to each of the extremities K, L of the water-bearing surface of the leaf; bisect these lines at U and V respectively, and draw perpendiculars to represent the total water pressure on each section. Each section is in equilibrium under the action of these forces : in one case, the water pressure, the heelpost reaction, and the stress across AB; in the second case, the water pressure, the mitre-post reaction, and also the stress acting across AB in the opposite direction. Join the points of intersection of the known forces to obtain the line of action of the resultant pressure at the section AB. Its magnitude may be determined by drawing a parallel line, *qo*, in the force diagram from the point *o* (fig. 18). By taking a series of sections in this way, it will be found that the locus of *q* is sensibly the arc of a circle, and therefore that, except in the case of very flat gates, the resultant pressure is so nearly constant as to be justifiably considered so without serious error.

Rise of Sill.—The 'rise of sill,' MT (fig. 17), varies in different cases from $\frac{1}{4}$ to $\frac{1}{6}$ of the 'span of the gates' or width of waterway. The vicinity of the latter limit is the more common, especially for large cylindrical gates, where a large rise would entail a correspondingly long and deep recess in the side walls.

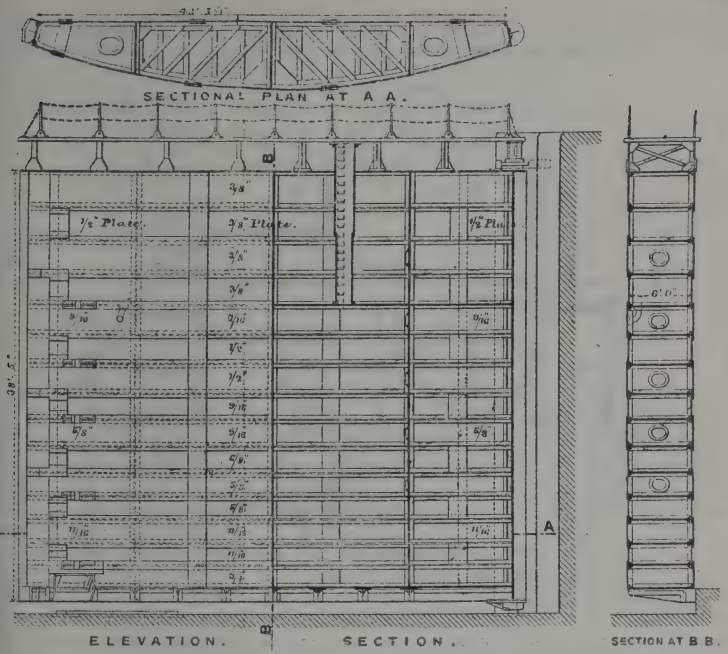

FIG. 19.—Dock Gates. (Steel.)

CAISSONS.

Caissons are sometimes preferred to gates on the ground that they do not absorb the length of side walls which is required to house gates when a passage is open. Furthermore, although the first cost of a caisson is undoubtedly in most cases greater than that of a pair of gates, yet if the cost of a swing bridge for vehicular traffic, which is a necessary adjunct in the case of gates, be also taken into consideration, the advantage will be found to lie with the caisson.

Caissons are mainly of two types: traversing and floating. Traversing caissons are rectangular boxes with a rectilinear motion either sliding or rolling. When withdrawn from the passage way, they are housed in a special chamber constructed in the side wall. Floating

* See footnote, page 1520.

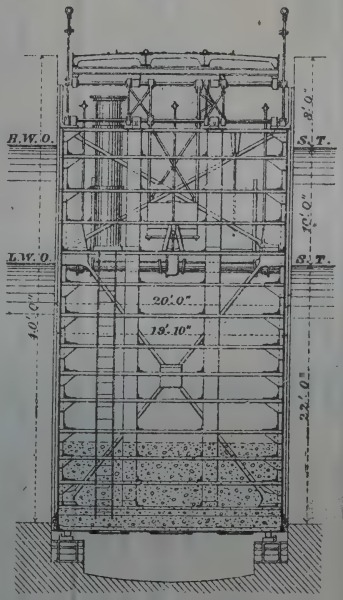

FIG. 20.—Section of Traversing Caisson.

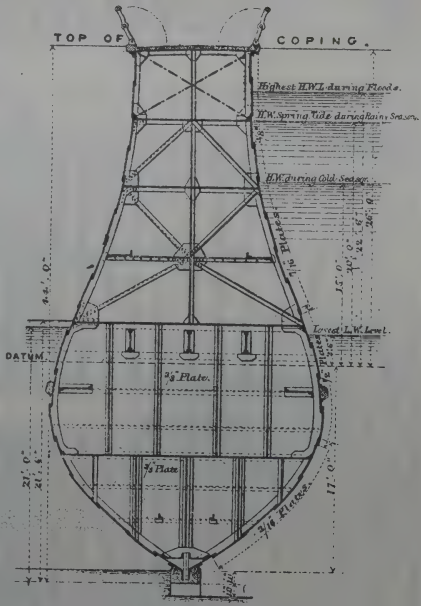

FIG. 21.—Section of Ship Caisson.

caissons are usually ship-shaped, having more or less the form of a navigable vessel, though the curvature of the sides varies very much with the depth of water in which they have to float. Floating caissons are not easy to manage in boisterous weather and strong currents.

QUAYSIDE APPLIANCES.

Quay Cranes.

For general work, quay cranes range in lifting capacity from 1 to 3 tons. The usual capacity is 30 to 40 cwts. It very often happens that the parcels from a ship's hold do not exceed 12 to 15 cwts., and, under these circumstances, a hydraulic crane of single and much higher power than this cannot be worked to advantage, as the consumption of pressure water is the same whether the load be infinitesimal or the maximum. Electric cranes are better adapted to variable loads, since the current consumed is directly proportional to the work done. On the other hand, the initial cost of electric cranes is some 30 to 40 per cent. more than that of hydraulic cranes, and the capital charges (interest and depreciation) are factors of considerable importance in estimating the relative economy.

Crane Types.—Quay cranes are generally movable and include several types.

(*a*) The ordinary crane, with a wheel gauge of 10 to 15 ft. running at quay level.

(*b*) The portal crane, with an arched base spanning one or more lines of railway sidings and admitting of the passage of rolling stock beneath the crane.

(*c*) The semi-portal crane, like an inverted L, with one leg or support running on a rail at quay level, and the back support carried by a rail at a higher level on an adjacent shed structure, the object being the same as in the case of the portal crane.

(*d*) The roof crane, carried entirely on the roof of the shed or warehouse.

Types (*a*) and (*d*) are adapted to cases where there are no sidings and type (*d*) where the shed is situated close to the edge of the quay.

The *cycle of operations* of a quay crane consists of lifting from a hold, slewing, depositing, and returning unloaded, and should, in ordinary cases, where the range of lift does not exceed 50 or 60 ft., be performed in about one minute. A good average under favourable conditions would be 50 cycles per hour; but spread over any lengthy period, this rate could hardly be maintained, for reasons entirely unconnected with the crane.

Speeds of Quay Cranes.—The ordinary speeds of 30 to 35 cwts. quay crane machinery are as follows:—

Lifting, full load	250 ft. to 300 ft. per min.
Lifting, light	350 ft. to 400 ft. per min.
Lowering, full load	400 ft. per min.
Lowering, light	150 ft. per min.
Slewing	one revolution in 25 or 30 seconds.

Luffing Cranes.—It is an important consideration in modern quayside work that cranes should have considerable outreach. Not only is it necessary for them to plumb the hatchways of vessels moored alongside, but in many cases it is desirable to command a barge or lighter beyond. This involves an outreach of 50 to 60 ft. from the face of the quay for even vessels of moderate beam, and entails a luffing or derricking movement of the jib. In view of the obstruction to radial movement caused by ships' yards and stays, the luffing of the crane jib has of recent years become an important feature of crane design. Formerly, the load was unavoidably raised during the inward travel of the jib with a correspondingly unnecessary expenditure of energy and time. This has now been obviated by the introduction of compensating luffing gear by means of which the load is carried at a uniform level throughout its range of travel.

* See footnote, page 1520.

Fixed Quay Cranes.—Fixed quay cranes are provided for dealing with special loads of considerable calibre. The powers provided are generally 5, 7, 10, 12, 15, and 25 tons, with appliances first-class ports ranging up to 150 or 200 tons. The rates of lifting are correspondingly slower about 150 ft. per min. for 5-ton cranes, 30 ft. per min. for 25-ton cranes, and 20 ft. per min. f 50-ton cranes.

(See also ' Wharf Cranes,' p. 909.)

Burtoning.

General cargo is mainly, and in fact almost universally, handled at North American por by a system known as Burtoning, which is the same in principle as the Union Purchase used English ports in conjunction with ships' gear. At American ports, the sheds are equipped wit cargo masts, generally prolongations of the shed front columns, rising to a height of 80 ft. or s above the quay level and supporting a longitudinal girder, or rail, running the full length of th shed. To this rail, at any selected point, a pulley may be attached, worked with a line, o extremity of which is joined, with a similar line from a pulley at the extremity of a ship's boom to the hook carrying the load. Two winches are required for operating: one for each line. Th ship's winch and line serve to lift the load from the ship's hold to deck level; the shed winc then takes charge, and by means of the shed line draws the load overside to the quay, where it lowered to the ground.

Floating Cranes.

Floating Cranes.—For the heavier lifts, floating cranes are often preferred. It is a convenienc to bring the crane to the ship rather than *vice versâ*. Against this must be set the greater initi and working cost of a floating crane. Floating cranes are provided at most first-class ports lifting power ranging from 25 to 100 or 150 tons. A floating crane recently built for a Japanes port has a working load of 200 tons at 105 ft. radius, 100 tons at 150 ft. radius, and 30 tons a 160 ft. radius. The heaviest lifts are performed at the rate of 5 ft. per minute. A revolutio takes 6 to 8 minutes.

A floating crane of 200 tons capacity is among the plant of the Mersey Docks and Harbou Board. It is an electrically-driven, derricking, and revolving crane, 154 ft. in length, 88 ft. i breadth, and 16 ft. in depth. The hoisting speeds vary from 6 ft. per min. for loads of 200 tons to 20 ft. per min. for loads of 60 tons. The highest point of the jib at its highest position is 246 f above the water-line, with a maximum radius for loads of 60 tons amounting to 183 ft., and fo loads of 200 tons, to 110 ft. The vessel is named the *Mammoth*; in conjunction with its outreach it is claimed to possess the largest lifting capacity of any existing floating crane. There are however, two floating cranes of 250 tons capacity at the Panama Canal.

Even for relatively small power lifts (5 tons or less) floating cranes are employed with advan tage at some French ports where the conditions are favourable for their use. The length of th crane pontoons are about 60 ft., a convenient dimension from the point of view of manœuvring the width increases (to prevent transverse oscillation) from 17 to 31 ft. in proportion as th power of the cranes increases from 1½ to 5 tons and the outreach from 25 to 50 ft. The height o the jib pulley varies from 53 to 65 ft. above water level.

(See also CRANE Section, p. 901.)

Transporters.

Transporters.—Where loads are uniform, can be readily handled, and have to be transmitte some distance, a transporter offers considerable facilities for dealing with them at high speeds ranging up to 1,200 or 1,500 ft. per minute. Quayside transporters have generally to be furnishe with hinged cantilever ends capable of being raised when out of action. The travelling motio is not necessarily rectilinear, curved tracks being employed where necessary.

Coaling Appliances.

Shipment of Coal.—Coal is shipped in a variety of ways, principally in this country b means of the hoist and tip or the coaling crane, but also by means of the belt conveyor, perhap more especially abroad. The belt conveyor requires a layout on the quay, which is not alway practicable or convenient in congested areas such as prevail at English docks. The hois raises the wagon to the requisite height and tips it at an angle of 45° or 50°, so that the content pass into a shoot. The crane lifts the wagon bodily, slings it over the ship's hatchway an there empties it. At Cardiff there is an installation on the Lewis-Hunter system by which th wagon, instead of being lifted, discharges its contents into a hopper placed in a pit on the quay and the hopper is lifted by the crane and lowered into the hold, where, being fitted with cone valves it can be emptied within a few inches of the floor. This system is adopted on account of the grea liability of the South Wales coal to breakage and comminution. The protection of coal fro breakage is of such importance that in nearly all cases where coal is tipped from a considerabl height, an anti-breakage crane is provided to lower the first few loads to the bottom of the hold.

Coal wagons in this country are commonly built to contain 10, 12, 15 or 20 tons of coal, an the gross weight ranges from 15 to 30 tons. To this must be added from 6 to 9 tons for th

cradle or platform. Consequently the lifting capacity of a coaling appliance will range between 20 and 40 tons according to the class of wagon dealt with. In certain special cases, as at Goole Docks, provision is made to lift a gross load of 50 or 60 tons, of which up to 40 tons is coal. The coal is brought along the Aire and Calder Canal in tanks, which are floated under the hoists.

In America the size of coaling wagons is very much greater and varies from 40 tons upwards to 100 or 120 tons. At South Wales ports attempts are being made to secure the general adoption of larger-sized wagons (20 ton capacity) than has hitherto been the practice.

The rate of coaling by an ordinary crane or hoist is from 300 to 450 tons and may even reach 600 tons per hour, but it is largely governed by the rate of trimming operations in the hold. The lifting and lowering of the wagons is done at speeds of between 100 and 180 ft. per minute and slewing at about one revolution per minute.

The belt conveyor consists either of a continuous rubber belt or of articulated steel plates. Of the two, the rubber belt has shown itself to be more convenient and more durable than the steel plating, the wear on which is considerable. Rubber belts are run at rates up to 600 or 700 ft. per minute, and they discharge the coal in a continuous stream. The belt is fed by means of a hopper recessed in the quay, into which the coal wagons are emptied. Installations in this country are of moderate proportions, the width of the belt running up to about 48 inches, but in the United States very much larger installations have been effected with belts of 60 ins. diameter. These belts travel up inclined ways to the summit of movable towers, whence the coal is passed on to a transverse belt discharging into the ship. Considerable expedition has been gained by the use of the mechanical trimmer, which is a short, rapidly rotating belt at the foot of the vertical shoot leading into the hold. The speed of the trimmer belt ranges up to 2,000 ft. per minute, and the acquired velocity projects the coal forward into all parts of the hold to distances up to 40 or 50 ft.

Ship's Bunkering.—The foregoing appliances are in vogue in connection with shipping coal cargoes. For the more moderate requirements of ships' bunkers, the loading appliance has generally to be brought to the ship's side, so as to proceed simultaneously with cargo discharging or loading operations. A good deal of bunkering is done by hand, with such primitive assistance as is afforded by baskets, ropes, pulley blocks, and winches, but the rate of coaling under such conditions is very slow and relatively costly—perhaps 2 tons per man per hour. There are a number of special floating machines provided at important ports for doing the work more expeditiously. A typical example, and one of the most modern designs, is the *Suisted Elevator*, built for the company of that name by *Spensers* (*Melksham*) *Limited*, and at work in the port of London. It is capable of handling 300 tons of coal per hour, but such a rate is manifestly only practicable under favourable circumstances; it could not be maintained with trimming operations going on.

Coal Discharge.—For the importation of coal, as also of ore, the grab is perhaps the appliance most commonly in use in this country, as also on a much more gigantic scale at the Lake Ports of North America. As used at English ports, the capacity of the grab runs up to 6 tons, with a total combined load, including the grab itself, of about 12 tons. At the Lake Ports of North America the standard type is a grab capable of taking a load of 12 tons, and the largest can take 17 tons. There is a 'bucket' for clearing up the holds at the close of operations, which when outspread has a span of 24 ft. between the bucket lips.

Grain Elevators.

Grain Elevators.—Grain is handled either by the bucket elevator and conveyor, or by the pneumatic elevator or suction apparatus. The latter has the advantage that the pipes, being flexible, can easily be taken to the furthermost parts of a ship's interior, and that no restrictions are imposed by variations in freeboard and depth of hold. The bucket elevator, though cheaper to construct and requiring less power, is hampered in working by the necessity of ploughing and trimming a preponderant portion of the grain—often as much as 80 per cent.—to the elevator leg. A special gang of competent men is required for the purpose, and this, of course, increases the cost of handling.

It is impracticable to do trimming with a ship's winch at a higher average rate than about 80 tons per hour. Beyond this limit the pneumatic machine becomes more effective, and pneumatic elevators can be constructed so as to give outputs of between two and three hundred tons per hour. On the other hand, conditions at ports are often such that so high a rate of discharge cannot be maintained, operations being governed by the rate of delivery. In practice something like 100 tons per hour is found to be the maximum consistent with effective working.

It has recently been realised that quite small pneumatic plants can be installed in warehouses, mills, etc., with extremely satisfactory and economical results in working. They vary in capacity from 15 to 50 tons per hour, and are generally driven either by the mill shafting or by electric current where available. Convenience in handling, absence of dust and avoidance of trimming are strong points in their favour.

An objection urged against the suction apparatus is that the surface friction of the pipes tends to injure some of the more delicate classes of grain, such as malting barley, but this drawback, for all practical purposes, has been eliminated of late years by the easing of bends and the removal of all internal projections in the pipes. In any case it should not be overlooked that the cutting and driving action of the buckets of a bucket elevator cannot be without some similar attritional effect.

Bucket elevators are either housed at the quayside or are mounted on barges, in both cases being fitted with derrick supports and suspension gear to enable them to be projected forward and set into the ship's hatchway. Elevator speeds generally range between 200 and 400 ft. per minute, but may be as high as 600 ft. per minute. Band or belt conveyors (p. 942) run at 300 to 600 ft. per minute, but for light grain, such as oats, the speed should not exceed 500 ft. per minute.

The development of the pneumatic operation of handling grain has been very marked in recent years. The slow-speed horizontal reciprocating steam-driven suction pumps have been largely superseded by quick-acting vertical pumps driven by internal combustion engines which are coupled direct to the pumps. A further development is the introduction of a multi-stage air exhauster, also driven in many cases by an internal combustion engine through speeding-up gear. This type is perhaps coming mostly into favour, especially where electric power is available.

Timber Appliances.

Timber, as received at ports, is generally divided into the categories of hard wood and soft wood, the former comprising logs of greenheart, teak, oak, etc., and the latter consisting chiefly of deals, battens, and boards of pine and spruce. Logs are handled overside by crane and either floated to timber ponds or conveyed on trollies to storage sites. In Liverpool a special arrangement of tandem axles is employed to which the logs are underslung.

Cargoes of deals may consist of from 150,000 to 300,000 pieces of various sizes and marks. This renders the use of apparatus of the conveyor type difficult and unsuitable, although such appliances have been successfully installed in certain cases. Generally speaking, cargoes of this class are best dealt with by steam cranes of moderate capacity (30 cwts. to 2 tons) which, arranged to run at right angles to the quay front, convey their loads to an adjacent storage ground at speeds up to 600 ft. per minute. The lifting speed is about 160 ft. per minute, and the slewing speed about 1½ to 2 revolutions per minute.

GRAVING AND FLOATING DOCKS.

A modern graving dock is an excavated chamber, two sides, one end and the floor of which are lined, either naturally or artificially, with watertight material, generally concrete with brick or granite facings and dressings. The remaining end is the entrance and is provided with a pair of gates or a caisson. After the entry of a ship, the entrance is closed and the water is pumped from within the dock, though, in certain cases, where graving docks are entered direct from a river or open waterway where tidal conditions prevail, the operation may be assisted, and sometimes be altogether effected, by the fall of the tide.

The floating dock is an open-ended, hollow structure of steel or iron, which, in order to receive a vessel, is sunk to the requisite depth, by allowing its air chambers to fill with water. When the vessel has been berthed, this water is pumped out, the dock rises bodily and so lifts the vessel above the water-line.

It is not altogether easy to make an effective comparison of the respective merits of graving and floating docks, on account of the wide divergence in the conditions to which each structure is specially applicable, and, although there are strong and convinced advocates for the general superiority of one or other of the two systems, a brief summary of the most salient considerations will show that it is scarcely justifiable to decide conclusively in favour of either. Floating docks are almost exclusively adopted at Hamburg, Rotterdam and other Continental ports; in Great Britain there are considerably more graving docks than floating docks.

A graving dock requires a good foundation at a reasonable depth, and a disposition of site which frequently involves the appropriation of a considerable area of valuable land.

A floating dock requires a sheltered position with an adequate depth of water, which, if not obtainable naturally, will have to be gained by dredging. The depth of water to be provided for a floating dock must be sufficient to cover the draught of the ship, the depth of the pontoons and the requisite clearances of a foot or two between keel and blocks and between pontoon and bed. Where there is tidal variation, the amount of this must also be added, if the dock is to be continuously accessible. In this country the tidal range may be anything up to 35 ft., and between 15 and 20 ft. is very general. For a modern ship of average size drawing 28 to 30 ft. of water, the pontoons would have to be at least 20 ft. deep. This means that the total depth of the floating dock berth below high water level would be about 70 feet, and there are circumstances under which dredging to so great a depth would be not merely difficult, but almost impracticable.

In sites where the foundation is defective, the depth of excavation required for the floor of a graving dock may easily equal the depth of the floating dock pontoons, and the difficulties and expense in these cases are just as pronounced.

The utility of a graving dock is measured by the linear dimensions of the largest vessel which it can accommodate. The weight of the vessel is relatively a matter of little or no importance.

On the other hand, the utility of a floating dock is gauged by its maximum lifting capacity and is independent of the exact size of the vessel. Floating docks can, and often do, take vessels

many feet in excess of their own length and, in the case of one-sided docks, in excess of their own width.

The size of the entrance of a graving dock is influenced by the cost of the gates, or caisson, to be used for closing it, and by the greatest width that can safely withstand the pressure of water. In floating docks these considerations do not enter into account.

Relative Costs of Graving and Floating Docks.*

Initial Cost.—The initial cost of graving docks, including pumping and general equipment, measured in terms of their serviceable dimensions (i.e. internal length by breadth of entrance by depth of water over blocks or sill), has varied from 1*s.* 3*d.* to 3*s.* 6*d.* per cubic foot, and, in a rough-and-ready way may fairly be taken for a modern concrete and granite dock of ordinary size, constructed in this country under normal conditions, on a pre-war basis, at 2*s.* per cubic foot.

The cost of floating docks is usually measured in terms of their lifting power, and varies inversely as the size of the dock, ranging from about 14*l.* per ton for a dock which would take small coasting ships to about 6*l.* per ton for one to take large Atlantic liners.

As regards time of construction, a graving dock of any importance could hardly be completed within less than eighteen months or even a couple of years, whereas a floating dock could be ready in half the time. The floating dock could, moreover, be constructed in any convenient locality and transported to its destination at some additional expense for towage and insurance. Many floating docks for the colonies are constructed in home shipyards.

Durability and Upkeep.—A stone or concrete graving dock is practically indestructible, and the only charge brought against it, in this respect, is that of outlasting its utility and becoming obsolete. This is, no doubt, true in regard to the class of vessel for which it is constructed; but, on the other hand, when the growth of shipping has left the graving dock too small for the larger vessels, it is still utilisable for those of smaller size. With the exception of the expenditure on the gates or caisson, which close the entrance, there is practically no maintenance outlay. It is all probably covered by an allowance of ½ per cent. per annum.

The life of a floating dock, considered as an iron or steel structure constantly afloat, will vary with its situation, some waters being more destructive than others. It may be fairly reckoned at from 40 to 50 years, and there is no reason why, with reasonable care and attention, the longer period should not be exceeded. The annual cost of maintenance estimated from several existing examples lies between 1 and 1½ per cent. of the capital outlay. Any cost of dredging required to keep the berth clear of mud deposits must be added to this allowance.

Working Cost.—The amount of pumping to be done in the case of a graving dock generally greatly exceeds that in the case of a floating dock—it may be as much as 3 or 4 times. In a floating dock only so much work is required to be done as is necessary to raise the vessel and the deck of the pontoon above water level. The graving dock chamber, on the other hand, has always to be completely dewatered, no matter what may be the size of the vessel occupying it and the smaller the vessel the greater the quantity of water to be pumped.

Small graving docks on the banks of a tidal river, in cases where time is unimportant, may be emptied of water by natural means. These cases are exceptional.

But even in the larger docks the cost of pumping is small in comparison with the capital charges. For one hundred dockings a year they probably do not amount to more than 10 or 12 per cent. of the whole annual expenditure.

Again, the pumps being only intermittently employed, one pumping station may be made to serve two graving docks, whereas each floating dock requires its own installation. Possibly an extra hand or two is also needed to attend to the valves of the floating dock in order to maintain an even keel during pumping operations, but generally all the valves are worked from a central position.

As regards general adaptability, floating docks have the advantage, already pointed out, of mobility, and they may be transferred from one port to another, whenever the circumstances require. This has already been done on several occasions to fall in with altered trade conditions, or for purposes of war.

A floating dock can be trimmed to take a vessel having a list which conceivably might interfere with its passage through a graving dock entrance with vertical sides. This operation was frequently performed during the war.

The mobility of a floating dock is not free from certain drawbacks. The dock may founder or be wrecked.

All these varying considerations point to the conclusion that there is scope for both graving and floating docks, and that each may be employed to better advantage than the other under some particular set of local conditions.

THE SOUTHAMPTON FLOATING DOCK.

The following particulars are extracted from a paper read before the Institution of Civil Engineers in January 1925, by Dr. E. H. Salmon (*Min. Proc. Inst. C.E.*, vol. 219) :—

Weights and Lifting Power.—The total net estimated weight of the dock in its final form was 18,990 tons, made up as follows :

	Tons.
Steelwork in hull, including mooring-booms	16,482
4½ per cent. for rivets	741
Joint bolts	17
Machinery	404
Fittings	736
Timber	407
Cranes, crane-rails, and collecting gear	183
Stores and spare gear	50
Proportion of weight of brow and moorings carried by dock	33
	19,053
Less half-weight of mooring-booms	63
Total	18,990

The above weight does not include any allowance for overweight and extras. From measured displacements of the finished dock its actual weight was found to be 19,330 tons. The displacement of the pontoon at Southampton (density of water = 35·09 cubic feet per ton) is 81,840 tons. At the conclusion of the test made to determine the lifting power of the dock, 1,530 tons of water remained in the pontoon. The true lifting power of the dock, therefore, is 81,840 — 19,330 — 1,530 = 60,980 tons.

Cost.—The original contract price for the dock delivered at Southampton was £375,000. The corresponding price of the steelwork in the hull comes to £17 per ton; the machinery, about £120 per ton; the fittings, about £32 per ton; and the timber, £22 per ton. A number of extra fittings over and above the original contract have been added, somewhat increasing the total cost of the finished structure. The above figures include the dock proper and mooring booms, but not the shore work, nor the preparation of the site.

Notes on Floating Docks.

(Contributed by Swan, Hunter, & Wigham Richardson, Ltd.)

The development of different types of floating docks in this country is largely due to Messrs. Clark and Standfield, Westminster, who have designed docks of almost every kind, and for service in many parts of the world.

Floating docks may be conveniently divided into two classes : (*a*) those which are not self-docking, or 'box docks,' and (*b*) those which can be self-docked.

(*a*) The *box dock* is double sided and of ⌊ ⌋ section. It has two side walls, and is the only form of modern floating dock which cannot be divided into more than one part for the purpose of self-docking. The two side walls and the bottom pontoon are one permanent structure. Box docks of great size have been built; for instance, the British Admiralty floating dock of 33,000 tons lifting capacity built at the Wallsend Shipyard and stationed at the River Medway.

BOOKS BY DR. BRYSSON CUNNINGHAM,

D.Sc., B.E., F.R.S. (EDIN.), M.INST.C.E.

THIRD EDITION, Revised and Enlarged. In Large 8vo. Handsome Cloth, Gilt. Pp. i-xviii+600. With 48 Folding Plates and 613 Illustrations in the Text. Price 42/- net.

THE PRINCIPLES AND PRACTICE OF
DOCK ENGINEERING

GENERAL CONTENTS.—Historical and Discursive.—Dock Design.—Constructive Appliances.—Materials.—Dock and Quay Walls.—Entrance Passages and Locks.—Jetties, Wharfs and Piers.—Dock Gates and Caissons.—Transit Sheds and Warehouses.—Dock Bridges.—Graving and Repairing Docks.—Working Equipment of Docks.—Reinforced Concrete in Dock Work.—Appendices.—INDEX.

'We have never seen a more profusely illustrated treatise. It is a most important standard work, and should be in the hands of all dock and harbour engineers.'—*Steamship*.

'A very meritorious addition to our technical literature. . . . It would be difficult to find a more thorough treatise on the subject of Dock Engineering.'—*Engineering*.

Companion Volume to the above. Third Edition, thoroughly revised and greatly enlarged. In Large 8vo. Pp. i-xvi+432. With 35 Plates, 24 Tables, and 294 Illustrations in the Text.

THE PRINCIPLES AND PRACTICE OF
HARBOUR ENGINEERING.

CONTENTS.—Introductory.—Harbour Design.—The Tides.—Surveying, Marine and Submarine.—Piling.—Stone, Natural and Artificial.—Breakwater Design.—Breakwater Construction.—Pierheads, Quays, and Landing Stages.—Entrance Channels.—Channel Demarcation.—INDEX.

'A truly monumental work. . . . We could wish for no more authoritative guide.'—*Shipping World*.

'We know of no other treatise which deals with the principles of harbour work in a more succinct way and with such authority.'—*Practical Engineer*.

Second Edition, revised. In Pocket Size. Leather. Pp. i-vii+319. With 144 Illustrations. 9/- net.

THE DOCK AND HARBOUR ENGINEER'S REFERENCE BOOK

Being a Compilation of Notes on various Matters Connected with

MARITIME ENGINEERING AND PORTS AND HARBOURS

CONTENTS.—I. General Administrative, Nautical and Physical Data.—II. Cost of Dock and Harbour Systems.—III. Harbour Construction.—IV. Dock Construction.—V. Quay and Dock Walls and Wharfs and their Equipment.—VI. Locks, Graving Docks, and Floating Docks and their Equipment.—VII. Dredging and Subaqueous Rock Removal.—VIII. Maritime Canals, Channel Rectification, Channel Demarcation, and Coast Defence.—INDEX.

'A vast amount of valuable information . . . with an excellent Index.'—*Liverpool Journal of Commerce*.

'The only book of its kind . . . is of special interest and value. Excellent judgment has been shown by the author in selecting the data . . . not only a book of reference, but also a book of instruction.'—*International Marine Engineer*.

LONDON CHARLES GRIFFIN & CO., LTD., DRURY LANE, W.C. 2.

F. 1539

(*b*) By a 'self-docking' type is meant a dock divided into sections any one of which can be lifted on the remainder of the dock for painting or repairs. The following are some of the various types of self-docking docks: the *Bolted-Sectional*, the *Sectional Pontoon* or *Rennie*, the *Off-Shore*, the *Havana*, the *Sectional Box*, the *Multi-Sectional*, and the *Depositing*.

The *Bolted Sectional Dock* combines the advantages of the great longitudinal strength of the '*Box*' type with facility for self-docking. This type is usually built in three sections of approximately equal lengths, the two end sections being stepped to form landings when carrying out a self-docking operation.

Fig. 22 shows, firstly, the whole dock assembled; secondly, the centre section lifted by the two end ones; and thirdly, one of the end sections lifted by the centre and other end section. Examples of the former type of dock may be seen at Port of Spain (Island of Trinidad), Rotterdam, at Callao in Peru, and at Sténia in the Bosphorus. (See fig. 27, page 1541.)

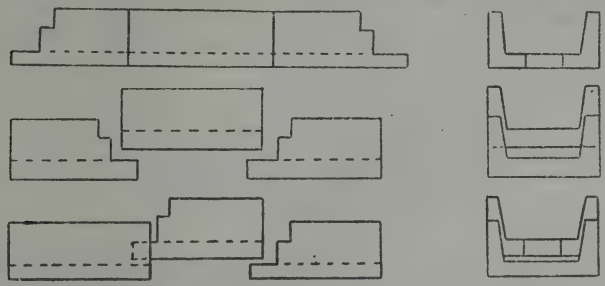

FIG. 22.—Bolted Sectional Floating Dock.

The Sectional Pontoon Dock (also called 'the Rennie Dock,' after its inventor), consists of a number of separate pontoons lying transversely to the length of the dock. Upon these pontoons and bolted to them rest two continuous side walls. The length of each pontoon, i.e. on the keel line, is such that when detached from the rest of the dock it can be passed end-wise between the walls of the latter and so lifted in the same manner as a ship. Each pontoon can be successively dealt with in the same manner. Fig. 23 shows first the whole dock assembled and then

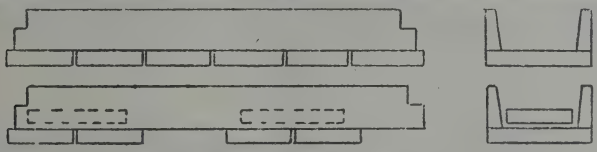

FIG. 23.—Sectional Pontoon Floating Dock.

two of the pontoons lifted by the remainder of the dock. This *Sectional Pontoon* type is very suitable for vessels of moderate dimensions, and owing to its form can easily be constructed in places where docks of other types could not be completed. The separate pontoons not being very large in size can be easily erected and launched, after which the walls can be built upon them. Examples of this type of dock were built at Wallsend-on-Tyne for the Government of Southern Nigeria, and for service at Saratov on the River Volga.

The Off-Shore Dock is an ingenious design patented by Messrs. Clark & Standfield in 1884; a well-known example of it was built at Wallsend-on-Tyne for a ship-repairing establishment at

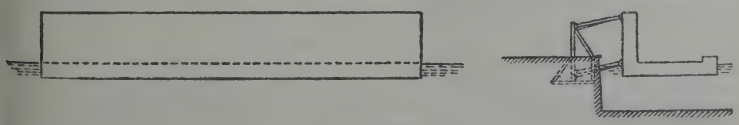

FIG. 24.—Off-shore Floating Dock.

Sunderland, and there is another good example of it also constructed by Messrs. Swan, Hunter, & Wigham Richardson, Ltd., at Penarth, near Cardiff. The off-shore dock (fig. 24), of which the end elevation is 'L' shaped, is very easily handled. The side wall is connected to the

shore by booms or girders hinged at each end. When the dock is sunk to receive a vessel the latter can enter the dock from either end or may be warped in sideways. It is then rapidly centred by telescopic side shores and supported underneath by mechanical bilge-shores. This type of dock is divided into two sections, and as it has only one wall one-half of the dock can be lifted, so to speak, in the lap of the other. Fig. 26 on this page illustrates the self-docking operation.

The *Sectional Box Dock* (fig. 25) combines the advantage of ease and simplicity in self-docking possessed by the Sectional Pontoon dock, with the strength of the solid or *Box* dock. The dock is divided, like the ordinary sectional dock, into sections of such a length that any one section can be

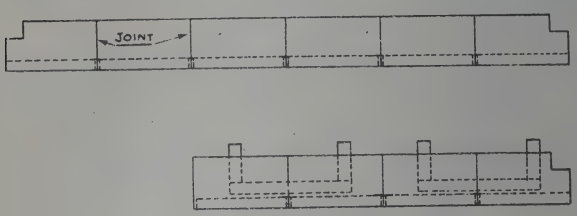

FIG. 25.—Sectional Box Dock.

turned round 90 degrees and docked on the rest of the dock. In the Sectional Box dock, however, the sections are all joined together by a strong, rigid joint of a similar type to that used in the bolted sectional docks running round the whole profile of the dock.

The *Multi-Sectional Dock* is a modification of the Sectional Dock type. In small docks it is not necessary to connect the bottom plating right across the width of the pontoon. The joints at the sections only occur, therefore, round the profile of the side wall, the spaces between the pontoons being decked over to form a continuous platform.

The *Depositing Dock* was designed as early as 1877, by Messrs. Clark & Standfield. In section it is 'L' shaped. The single side wall is continuous, but the bottom pontoon is made up of a series of 'fingers' with spaces between them (fig. 26). The necessary stability is given to the dock

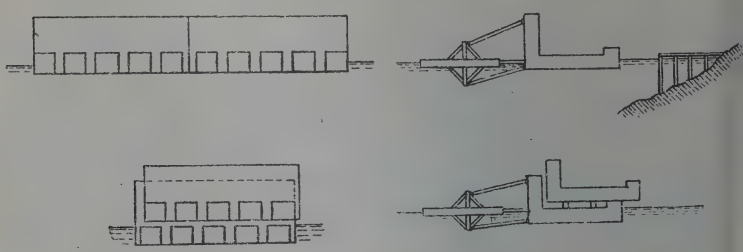

FIG. 26.—Depositing Floating Dock.

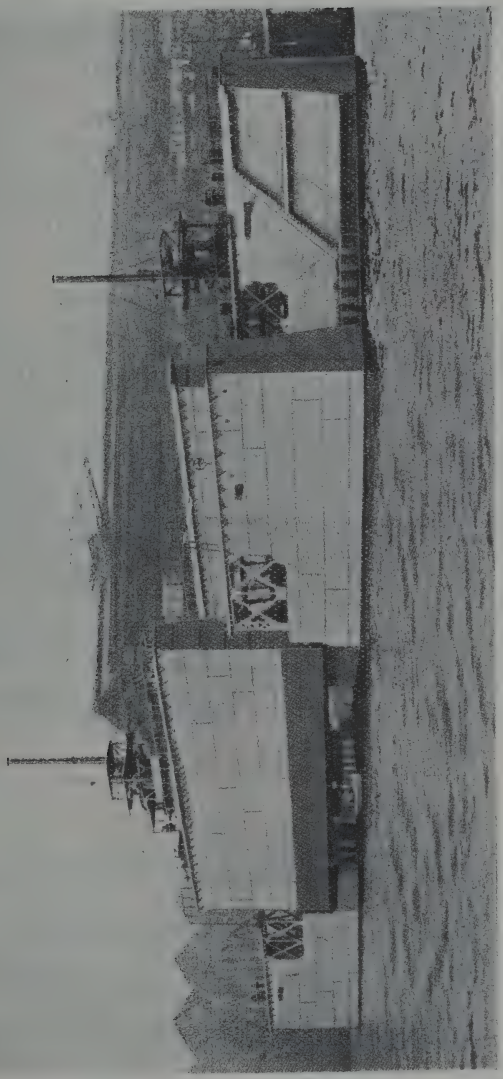
by means of parallel booms hinged at each end and connected to a floating outrigger. This type of dock can not only dock vessels, but owing to the peculiar construction of the bottom pontoon is enabled to deposit them on a gridiron formed by groups of piles. There are spaces between each set of piles of such a width as to admit the 'fingers' of the dock. The dock carrying a ship is pushed forward so that the 'fingers' are engaged between the piles and then on sinking the dock the ship is left upon the gridiron. The wall of the dock is divided into two equal lengths either of which can be docked by the other as in the case of the off-shore type.



FLOATING DOCK.

FIG. 27.—Bolted-Sectional Dock.

(Built by *Swan, Hunter, & Wigham Richardson, Ltd.*, Wallsend-on-Tyne, England.)

Self-docking operation; centre section lifted by the two end-sections.

Depositing docks at Kobe and Barcelona have been used for the purpose of lifting large, hollow ferro-concrete blocks for harbour construction. These were built upon the depositing grids, lifted off by the dock, and finally floated off so that they could be towed to their final position and sunk there. In the case of the Kobe dock, some of these monoliths were 120 ft. long by 41 ft. high, and weighed as much as 2,200 tons. In this way the difficulty of launching such large masses was avoided and much expense saved.

DREDGING.

Modern dredging appliances may be summarised under two classes, each with several subdivisions.

Class I.—Digging dredgers, comprising (*a*) the ladder, or elevator, dredger, with a continuous band of buckets; (*b*) the dipper dredger, with a single bucket at the extremity of a long arm, or lever; and (*c*) the grab or grapple dredger, with a drop bucket suspended at the end of a chain.

Class II.—Suction or hydraulic dredgers, comprising (*a*) the sand pump; and (*b*) the suction cutter dredger.

Rock cutters are not dredgers, but constitute an auxiliary class which will be treated separately.

Ladder Dredgers.

Ladder Dredgers, or Elevator Dredgers (sometimes in Europe called bucket dredgers), are characterised by high power and great serviceability under nearly any conditions. They are adaptable to the removal of every variety of material except the harder kinds of rock. The principle upon which they are constructed is that of an endless chain of buckets travelling in an elliptical path about two pivots, or tumblers, set one at each extremity of an inclined plane. The buckets excavate material at the lower tumbler and discharge it into a shoot while passing over the upper tumbler.

Single Ladder v. *Double Ladder Dredgers.*—Dredgers of the ladder type have either one or two ladders. In single ladder dredgers, the ladder is situated along the centre line of the vessel; in the other case, the ladders are placed at each side.

Single ladder dredgers are most in favour for ordinary operations. In machines of the same power, they have the advantage of few working parts and of less working friction. As seagoing craft, they possess a more convenient outline, and their lesser width enables them to pass through narrower waterways and lock chambers. But they cannot work so closely to a quay wall as side ladder dredgers, and, if any breakdown occurs in the chain of buckets, the whole dredger is thrown out of action, whereas, with the double ladder dredger, this is not necessarily the case.

Capacity of Ladder Dredgers.—The capacity of the buckets of ladder dredgers ranges from 5 to 54 cubic ft., but, generally speaking, about 35 cubic ft. is looked upon as the maximum size consistent with convenient utility. A moderately sized dredger, with buckets of 20 to 25 cubic ft. capacity, travelling at speeds from 15 to 20 ft. per minute, and working in water of depths up to 50 ft., may be expected to raise from 400 to 500 tons of stiff clay per hour; in suitable material, such as ballast and gravel, the rate obtained may be as high as 1,000 tons per hour. The most powerful dredgers can double this performance.

Examples of Ladder Dredgers.—The following particulars relate to the 'Corozal,' built in 1911 for the U.S. Government, for work on the Panama Canal:—

Dimensions.	Ft.
Length on load water line	239
,, between perpendiculars	259
,, over all	268¾
Breadth moulded	45
Depth moulded	19½
Draught fully loaded	15½

Propelling speed: 10 knots.

Dredging capacity: 1,200 cubic yds. of mud and sand per hour.

Buckets: Two sets; one of 54 cubic ft. capacity for soft material and one of 35 cubic ft. for stiff clay.

Maximum dredging depth: 50 ft.

The vessel is a hopper dredger, i.e. she discharges into herself instead of into an independent hopper ranged alongside.

The 'Silurus,' built by Messrs. W. Simons & Co., Ltd., Renfrew, is a twin-screw bucket hopper dredger of the following dimensions:

	Ft.
Length between perpendiculars	260
Breadth moulded	46
Depth moulded	20

Propelling speed	8½ knots.
Dredging capacity	2,200 tons per hour.
Buckets, two sets	one of 42 cu. ft. and one of 22 cu. ft.
Maximum dredging depth	50 ft.
Hopper capacity	1,500 tons.

Utility of Ladder Dredgers.—Although the serviceability of ladder dredgers does not extend to the removal of hard rock, yet they are capable of scraping away the surface of the softer varieties of sandstone and chalk, and, for this purpose, the bucket edges are sometimes fitted with spikes or tines. A ladder dredger works admirably in marl and stiff clay, and no difficulty even is found in dealing with heavy boulders which are frequently encountered in clays of glacial formation. The buckets of a first class dredger will readily lift stones weighing from 30 cwts. to 2 or even 3 tons apiece, bringing them up to the surface and within the range of a deck crane. As illustrative of the character of the material dealt with in many cases, the following particulars may be cited, relating to twelve months' work on the river Tees. A quantity of 417,963 cubic yds. was dredged at a cost of 22,432*l.*, equivalent to about 1*s.* 6¾*d.* per cubic yd. About two-thirds of this was hard, boulder clay and there were removed therefrom 1,651 stones, varying in weight from 5 cwts. to 4 tons apiece, of which 1,523 were raised by the dredgers unaided by divers; and, in addition, there were 19 tree trunks, ranging in length from 10 ft. to 20 ft., 16 tree roots and stumps, and 107 miscellaneous obstructions.

Dipper Dredgers.

Dipper Dredgers.—The dipper dredger is almost purely an American type, and has not yet been found in Europe. It is mainly employed on the great lakes of the Northern Continent of America, and on river beds and channels when the working depth does not generally exceed 20 ft. or so, and where space for manœuvring is somewhat restricted. This is accountable for by the fact that the dredger is not manipulated by chain moorings, as in the case of the ladder dredger, but is maintained in position by vertical spuds, or posts, which pass down through the vessel to the bottom of the channel, and are raised and lowered as occasion may require. The dipper arm itself assists in manœuvring, being allowed to remain on the bottom while the position of the spuds is changed.

Capacity of Dipper Dredgers.—The single bucket, or scoop, at the end of the lever arm has a capacity ranging from 1 to 12 or 15 cubic yds. The bucket is operated in a curved upward sweep by suitable gearing, on the same principle as a steam navvy or land excavator. The speed of a good dipper dredger in sheltered inland waters is from 30 to 40 seconds per dipper load, and on the sea coast from 40 to 50 seconds. For hard material, the bucket, as in the case of the ladder dredger, is fitted with teeth.

Examples of Dipper Dredgers.—The following particulars relate to a very large dredger, the 'Onondaga,' which worked in New York Harbour:—

Length of hull	140 ft.
Breadth ,,	50 ft.
Depth ,,	15 ft.
Capacity of dipper bucket	12 cubic yds.
Dredging depth	50 ft.

Size of dipper arm: 80 ft. long by 36 ins. square.
Spuds: Four timbers, 80 ft. long by 5 ft. square.
The dipper arm and spuds are both of Oregon fir.
Engines: Double cylinder, condensing.
Cylinders: 20·5 ins. diameter by 24 ins. stroke.

Another instance of a dipper dredger at Montreal Harbour:—

Length of hull	90 ft.
Width ,,	36 ft.
Depth ,,	10 ft.
Capacity of dipper bucket	7 cubic yds.
Dredging depth	40 ft.
Diameter of hoisting rope	2¼ ins.
Maximum pull on dipper	120,000 lbs.

Forward spuds: Single timbers (Douglas fir) 60 ft. by 42 ins. square.
Engines: Double cylinder (16 ins. by 18 ins. stroke) non-condensing.

Two dipper dredgers, the 'Gamboa' and the 'Paraiso,' each with buckets of 15 cub. yds. capacity, were built by the Bucyrus Co. in 1914 for work on the Panama Canal.

These dredgers have a displacement of about 1,500 tons, and the hulls, which are of steel, have an over-all length of 136 ft., a width of 44 ft., and a depth at bow of 15½ ft. and at stern of 13½ ft. Each dredger has two dipper buckets, the larger, of 15 cub. yds. capacity, for soft material, and the smaller, of 10 cub. yds. capacity, for harder material. The buckets, of ¾ in. plate, have lips of manganese steel, 2 ins. thick, which are 50 ins. deep at the centre, reduced to 9½ ins. at the back edges. They have no teeth. The handles are of Oregon fir, 72 ft. long.

The rate of working is said to average 6,000 cub. yds. per day each, in two 8-hour shifts.

A dipper dredger at work in Bombay Harbour has a bucket capacity of 6 cub. yds., dredges to a depth of 40 ft., and is capable of lifting boulders of over 12 tons weight.

Comparison of Dipper Dredger with Ladder Dredger.—Compared with the ladder dredger the dipper dredger is not quite so serviceable a machine for all-round purposes, and, for the more intractable kinds of material, it has been demonstrated that the former is more efficient than the latter. Thus, in excavating a channel in indurated clay in the St. Lawrence River, dipper dredgers of the most powerful design failed and were replaced by a ladder dredger which completed the work in a satisfactory manner.

The Grab or Grapple Dredger.

The Grab or Grapple Dredger has a bucket which consists of two or more curved plates, or jaws capable of opening and closing under the action of suitable gear. The grab is suspended from the jib head of a crane which does the requisite raising and lowering. The working is actually done very largely under the influence of gravity, the bucket being allowed to fall with open jaws under its own weight and to bury itself in the ground, where the jaws are closed and the bucket with its contents is then withdrawn. The principle of the grab is simple, but there are many complex adaptations in practice. Thus, the appliance may be worked by one or by two chains, each of which arrangements admits of several variations, so that there are quite a number of different machines on the market, each possessing special characteristics and advantages.

Comparison of Single and Double Chain Grabs.—The drawback of a double-chain grab is that it cannot be fitted to an ordinary crane; but, on the other hand, it has less intricate and less delicate mechanism, and, consequently, does not run the same risk of getting out of order. With two chains, moreover, there is less likelihood of the bucket being lost through fracture of the hauling gear. There is the further consideration that in many, if not most, single-chain grabs, the full height of lift has to be made before the grab can be opened in order to discharge its contents. Double-chain grabs can discharge at any stage of the lift. This advantage is shared by a few of the single-chain systems. Its importance lies in the fact that the grab might close upon some immovable object below water, and therefore necessitate the sending down of a diver, unless the jaws can be opened mechanically in that position.

Utility of Grab Dredgers.—The grab is not a suitable appliance for extensive operations. It is best adapted to dealing with material in confined and awkward situations inaccessible to other types of dredger. It is thus excellently suited for the removal of mud and silt in the vicinity of dock entrances and passages. Silt is generally of so impalpable a character that any disturbance of the water in which it lies causes it to rise in suspension, and renders it difficult of removal. The grab proves a most effective appliance for dealing with this soft material, entrapping it with the least admixture of water and the least alteration in consistency. Moreover, the grab is an extremely convenient implement for picking up miscellaneous articles which find their way to the bottom of docks; logs of hard wood, rails, coal, bales of hay and wool, barrels of nails and cement, hoop iron, etc.

Capacity of Grab Dredgers.—Grabs are constructed of a capacity up to 10 cubic yards, but for general purposes the most useful size lies between 70 and 120 cubic ft. They work very successfully in water up to 50 or 60 ft. in depth, at a speed of about one dip per minute, raising in this way from 150 to 250 cubic yds. per hour.

Examples of Grab Dredgers.—Several excellent examples of this class of dredger are constantly at work in the Liverpool docks. The grabs are mounted on barges of 1,100 to 1,400 tons hopper capacity. There are four 5-ton or 7-ton cranes of 16 ft. and 19 ft. radius respectively on each barge, each actuating a grab of 70 or 115 cubic ft. capacity. The principal dimensions of the vessels are:—

1,100 ton barges	200 ft. long by 35 ft. beam by 15½ ft. deep.
1,400 ton barges	225 ft. long by 38½ ft. beam by 16 ft. deep.

The speed of the barges is about 11 knots.

Bag and Spoon Dredging.—This notice of dredging appliances would be incomplete without some reference to a very rudimentary form of apparatus still practised in restricted areas and where operations are on a small scale. This apparatus consists of a strong leather bag of a capacity of from one-half to one cubic yard attached to a steel rim at the end of a stout spar, or pole, from 20 ft. to 35 ft. long. The bag is kept at the bottom by means of the pole, while it is drawn along the surface by a line attached to the rim. The operation is performed by manual labour, and about half a dozen men are required to man a barge for the purpose. The quantity raised and loaded into the barge will range from 60 to 100 cubic yds. per day. The appliance is really only suitable for dealing with mud in timber ponds and in canals.

Suction or Hydraulic Dredgers.

Suction or Hydraulic Dredgers.—Turning now to the second class of dredging plant, the suction or hydraulic type may be described as consisting essentially of a continuous pipe, or tube, through which material is drawn up by suction from the bottom and discharged either into a hopper or through a long pipe line to a depositing site some distance away. The first application of the principle was to the removal of sand—hence the name Sand Pump—but it has since had a much wider application. As regards sand, the method proved extremely effective from the first, the light granular nature of the substance lending itself admirably to easy incorporation with the body of water flowing into the pump intake. Such difficulty as has been experienced has been merely in regard to securing the deposition of the sand within the hopper, the tendency being for a large proportion to flow out over the sides with the escaping water. Considerable reduction in this unremunerative pumping has been made by giving the effluent stream as long a distance to travel as possible and providing the channel with adjustable coamings.

Sand Pump Dredgers.

Sand Pump Dredgers.—For the purposes of suction dredgers, centrifugal pumps are universally employed, and of these, those with a single inlet have an advantage over pumps with a double inlet, in that there is less concussion and interference with the flow. A double inlet pump, on the other hand, disposes of any question of balancing, which has to be met in a single inlet pump by thrust bearings. The most efficient peripheral speed is stated by the Mississippi River Commission to be about 50 ft. per second. The form of the nozzle of the intake pipe materially influences the percentage of sand raised which may be anything up to 50.

Examples of Sand Pump Dredgers.—The largest sand pump dredger in existence at the present day is the 'Leviathan' of the Mersey Docks and Harbour Board. Her dimensions are 465 ft. 9 ins. long between perpendiculars, by 69 ft. wide by 30 ft. 7 ins. deep moulded. She is fitted with four suction pumps, each of 42 ins. diameter, and is capable of filling herself with 10,000 tons of clean sand in 50 minutes from a maximum depth of 70 ft. The speed of the vessel is 10 knots. On arrival at the depositing ground, she discharges herself in 10 minutes through large cylinders extending from valve openings, 5 ft. 6 ins. diameter, in the bottom of each hopper to deck level. These valves have a lift of 4 ft. and are operated by hydraulic rams. At work on the bar and entrance channel of the Mersey, the Leviathan pumps up over 12 million tons of sand per annum.

The following particulars relate to the 'Coronation,' a vessel in the same service :—

Length between perpendiculars	332 ft.
Breadth moulded	52·7 ft.
Mean draught, loaded	17·2 ft.
Maximum dredging depth	65 ft.
Speed	10 knots.
Loaded capacity	3,500 tons.
Pumping capacity	4,500 tons per hour.
Suction pipes (two)	36 ins. diameter, 81 ft. long.
Propelling engines	2,000 i.h.p.
Pumping engines	800 i.h.p.
Cylinders of propelling engines	19 ins., 30 ins., and 49 ins. diameter by 30 ins. stroke.
Cylinders of pumping engines	12 ins., 20 ins., and 32 ins. diameter by 18 ins. stroke.

Suction Cutter Dredgers.

Suction Cutter Dredgers.—The success attending the introduction of the sand pump led to an investigation of the possibility of dealing with less tractable material by the same means. Water jets for loosening and disintegrating hard and compact strata were added, and some satisfactory results being obtained, the further step of introducing rotary cutters was taken. There was found to be little difficulty in treating in this way earth of a marly or brittle nature, easily resolvable into disconnected particles. Trouble, however, was experienced in dealing with clay and tenacious material, which clogged the cutters and choked the intake. Eventually this was overcome by the evolution of cutter blades of a suitable form and pitch.

Capacity of Suction Cutter Dredgers.—Suction cutter dredgers are now constructed capable of removing over 1,000 cub. yds. of stiff clay per hour. In material usually dealt with by bucket dredgers, the cutter suction and discharging dredger 'Lord Willingdon' at Cochin dredged and discharged, through 4,500 ft. of pipe line, 1,500 cub. yds. per hour over an extended period, and on occasion this output has been considerably exceeded.

Use of the Pipe Line.—The use of the pipe line for discharging purposes is becoming very general, especially in cases where it is practicable to use the dredged material for filling and embankment purposes. These lines are often of great length. A dredger working at Oakland, California, U.S.A., has successfully delivered material through 6,170 lineal ft. of 20-in. diameter pipe. Diameters reach as high as 42 ins. when altogether afloat, and 30 ins. to 36 ins. when partly ashore. In calm water thin sheet tubing will suffice, but in exposed situations long lengths of solidly built sections must be provided. The carrying capacity of a 36-in. pipe with 80 per cent. of solid matter conveyed at a rate of 10 ft. per second would be 7,400 cubic yds. per hour. Sand causes considerable wear and abrasion of the piping and requires a high percentage of water with greater velocity to keep it in suspension. Clay, from its unctuous nature, exercises far less frictional resistance and is sometimes rendered sufficiently fluid by 10 per cent. of water. A velocity of 7 ft. per second for clay and mud, and 10 ft. per second for sand, has been found to give good results.

Compound Dredgers.

Compound Dredgers.—A compound type of dredger has recently been introduced fitted with both the suction, or suction cutter, apparatus and a bucket ladder. This enables the dredger to be applied to a wide variety of material in the most effective manner. The bucket ladder is generally placed in the centre well and the suction apparatus at the sides of the vessel, but in some cases the suction pipe is also centrally situated.

Example of Compound Dredgers.—The dredger 'La Loire,' built for service on the river of that name, is a twin screw combined bucket and suction dredger with cutter gear and pipe line shore delivery. Her dimensions are 173 ft. 10 ins. in length by 32 ft. beam by 14 ft. deep. She is fitted with two centrifugal suction and force pumps, capable of raising material from a depth of 25 ft., and of driving it ashore through floating delivery pipes about 30 ft. long and 24 ins. diameter. The suction pipe is 26 ins. diameter and works, together with the bucket ladder, in a centre well.

The cutter has a diameter of 6 ft. 10 ins. and is driven at 12 revolutions per minute, the engine running at 140 revolutions.

The bucket ladder enables the dredger to work to a depth of 52 ft. 6 ins. The buckets have a capacity of 27½ cubic ft. They are driven at a speed of 16 buckets per minute with the engine running at 170 revolutions.

Both suction and bucket apparatus enable the dredger to excavate her own flotation in advance.

The machinery consists of two complete sets of direct acting, triple expansion surface condensing, reversible propelling engines, each arranged to drive a centrifugal pump as well as the bucket dredging gear. Each set of engines indicates about 450 h.p. when running at 170 revolutions per minute. The cylinders are 13 ins., 21 ins., and 33½ ins. by 18 ins. stroke.

The cutter gear is driven by means of belting from a separate engine of 200 h.p., which also serves for a centrifugal pump delivering spoil from the buckets into the upper part of the shoot.

For the purpose of working the bucket dredging apparatus the suction pipes and cutter gear are dismounted, but in deepening the bed of the river Loire the latter proved so effective that over 13 million cubic yds. of alluvial material have been removed without recourse to the bucket apparatus.

Hopper Service.

When dredged material has to be removed some distance to a depositing ground it is excavated by the dredger into its own hopper, or into hopper barges ranged alongside.

A combined hopper dredger costs less in initial expenditure and subsequent upkeep than a separate dredger and hopper of corresponding capacity, and it occupies less valuable space in a crowded waterway.

On the other hand, it involves the discontinuity of dredging operations and the frequent getting out and taking in of moorings. This latter consideration is of importance more to dredgers of the bucket ladder type.

On the whole, it is found expedient on undertakings of considerable magnitude, and in cases where the depositing ground is several miles distant from the dredging site, to maintain a fleet of hopper barges in attendance on bucket ladder dredgers. Suction dredgers, when they do not discharge through a pipeline, more commonly are compound vessels with self-contained hoppers.

Capacity of Hopper Barges.—Barges are constructed capable of receiving from 500 to 1,000 cubic yds. of dredged material (say 650 to 1,350 tons) and of making journeys to sea and back at speeds of 10 to 11 knots.

Example of Hopper Barge.—A typical barge of 800 tons capacity has a length of about 190 ft., breadth 30 ft. and depth 14 ft. The engines are triple expansion, surface condensing, with cylinders 16½ ins., 26 ins. and 43 ins. diameter by 27 ins. stroke, which at 110 revolutions per minute develop 820 i.h.p. and give a speed of 10 knots, steam being supplied at 180 lbs. per sq. in. from marine multitubular boilers.

Cost of Dredging Plant.*

The following figures may be useful as approximate indications of the cost of dredging plant which must, of course, vary from time to time with fluctuations in the price of material and the engagements of the shipbuilding yards.

Ladder Dredgers.—A 5 cubic ft. bucket, single ladder dredger, capable of raising 150 tons of soft material per hour from a depth of 40 ft., has cost in round figures 7,000*l.*

A 15 cubic ft. bucket, single ladder dredger, capable of raising 400 cubic yds. of sand, gravel and clay per hour from a depth of 45 ft., has cost about 27,000*l.* and was constructed in six months.

A one cubic yd. bucket, single ladder dredger, capable of raising 750 cubic yds. of ballast per hour from a depth of 55 ft., has cost about 43,000*l.*, and was built in nine months.

Dipper Dredgers.—A one to two yard dipper dredger costs from $8,000 to $12,000; say 1,600*l.* to 2,400*l.* The hull is of timber, about 60 ft. long by 25 ft. wide, with a draught of 3 ft.

A 3½ to 4 cubic yd. machine dredging to a depth of 30 to 35 ft., would cost about $80,000 to $90,000, say 16,000*l.* to 18,000*l.*

A 10 cubic yd. machine dredging to a depth of 35 ft. would cost about $130,000 to $140,000, say 26,000*l.* to 28,000*l.*

* See footnote, page 1520.

Grab Dredgers.—A twin-screw hopper dredger, with a hopper capacity of 1,200 tons, and fitted with 5 hydraulic grab cranes each of 5 tons bucket capacity, working to a depth of 47 ft., has cost about 35,000*l.*

Suction Dredgers.—A suction hopper dredger with a hopper capacity of 70,000 cubic ft., capable of raising 3,500 to 4,000 tons of sand per hour from a depth of 70 ft., has cost about 75,000*l.* A 2,000 ton suction hopper dredger would cost about 50,000*l.*

Compound Dredgers.—A sea-going hopper dredger, fitted with both ladder buckets (18 cubic ft.) and suction pumps, and capable of dredging by the former means 400 cubic yds. per hour, and by the latter means 650 cubic yds. per hour, from a depth of 50 ft., has cost about 52,000*l.*

Hopper Barges.—A steam hopper barge of 800 cubic yds. capacity, with a speed of 11 knots, costs from 18,000*l.* to 20,000*l.*

Cost of Dredging Operations.*

Conditions and circumstances vary with each locality, so that it is difficult to give reliable figures for general guidance. Sand pump dredging can be done for as little as 1*d.* per cubic yd. or even less, and grab dredging from 2*d.* to 6*d.*, but a very great deal depends on the distance the spoil has to be carried. In bucket dredging, either by ladder or dipper, the range of cost is considerable, depending in addition, as it does, on the kind of material dealt with. The following are a few collected records from various sources :—

BOMBAY HARBOUR AND DOCKS.

Total Maintenance Dredging during Five Years, 1920–1925.†

Costs exclusive of Interest and Depreciation on Dredging Plant.

Location.	Total Quantity Lifted : Cubic Yards.					Cost per Cubic Yard : Annas.				
	1920–1921	1921–1922	1922–1923	1923–1924	1924–1925	1920–1921	1921–1922	1922–1923	1923–1924	1924–1925
Alexandra Dock	24,210	297,500	20,380	144,800	388,000	9·23	7·78	8·01	5·78	6·62

Port Natal.—The following particulars (extracted from a paper by Mr. William Brown on 'Recent Progress in Dredging Machinery'; *vide* Min. Proc. Inst. C.E., vol. cciii.) relate to the performances of the four principal dredgers at Port Natal, Durban, within a period of several years ended December 31, 1914. The costs include all charges for working, maintenance, insurance, depreciation and interest on capital. The price of coal consumed by the dredgers was low, and seldom exceeded 8*s.* per ton. The three large vessels (Labrus, Cetus, and Nautilus) each employed fourteen Europeans, eighteen Kaffirs, and eleven Indians, or a total complement of

* See footnote, page 1520.

† Extract from paper on 'Maintenance Dredging in Bombay Harbour and Docks,' by E. L. Everatt, *Min. Proc. Inst. C.E.*

forty-three hands, at an annual cost of about 3,850*l.* per vessel. 'With the possible exception of Liverpool, no port hampered by sandbars has made such progress in comparatively recent years as Durban.'

PARTICULARS AND WORKING COST OF SEA-GOING PUMP DREDGING PLANT AT PORT NATAL.

Name of Dredger.	Year Built.	Tonnage.		Hoppr. Capacity (Tons of Sand).	Pumping Speed (Tons of Sand per hour).		Average Spoil handled per ann. (Tons).	Average number of days worked per ann.	Cost per ton handled. (*d.*)	Remarks.
		Net.	Gross.		Contract.	Record.				
Labrus .	1911	1,215	2,097	2,000	2,000	2,000	719,500	244	6·806	Worked exclusively in stiff clay, being fitted with patent clay cutter. All spoil dredged repumped ashore from ship's hoppers for land reclamation.
Cetus .	1905	1,327	2,414	3,000	3,000	7,430	2,151,000	232	2·227	Largely employed for bar work. Spoil mostly coarse loose sand and fine stone, all dumped at sea, two miles from harbour entrance.
Nautilus	1903	1,050	2,034	2,500	3,000	7,894	1,466,000	247	3·109	Employed chiefly on maintenance and deepening of harbour bed and channels. Material mostly fine sand, with occasional admixture of loose clay and mud, all deposited at sea two miles from harbour entrance.
Snipe .	1903	180	265	200	300	340	358,000	256	3·201	Used for clearing up wharf and quay berthage, cutting and maintaining boat channels, occasional reclamation, etc. Spoil deposited within harbour.

Panama Canal.—During 1910 the sea-going suction dredgers 'Culebra' and 'Caribbean' removed 6,083,902 cubic yds. at a cost of 3·7*d.* per cubic yd. The ladder dredger 'Marmot' removed 1,372,665 cubic yds. at 7·82*d.*, and dredger No. 5 removed 560,622 cubic yds. at 13·65*d.* per cubic yd. The small 5 cubic yd. dipper dredgers 'Cardenas' and 'Mindi' removed 1,013,485 cubic yds. at 27·89*d.* per cubic yd. and the 20-in. pipe-line suction dredgers, Nos. 82 and 85, dealt with 2,472,822 cubic yds. at a cost of 14*d.* per cubic yd. During a period of twelve months ended May, 1916, the dipper dredgers 'Gamboa' and 'Paraiso' each removed over 2,900,000 cubic yds., at costs varying from 2·25*d.* to 5·45*d.* per cubic yd., including operation and maintenance.

Mississippi River.—In 1907 three pipe-line suction-cutter dredgers dredged 1,279,000 cubic yds. at 4·12*d.* per cubic yd. including the cost of idle time. In 1908 the same dredgers accounted for 989,000 cubic yds. at 5½*d.* per cubic yd.

New York Harbour.—In 1909, the sea-going suction dredgers 'Manhattan,' 'Atlantic,' 'Raritan,' and 'Navesink,' removed 10,786.638 cubic yds. at a total cost of $424,734 (say 85,000*l.*) or at the rate of 1·97*d.* per cubic yd. made up as follows: Dredging, 1·785*d.*; surveys and examinations, ·125*d.*; contingencies and supervision, ·06*d.* The 'Delaware' removed 1,675,562 cubic yds. at a total cost of 2·39*d.* per cubic yd.

River Thames.—The contract cost of removing hard material (ballast and clay) by ladder dredger from the Thames below London Bridge has ranged at various times before the war from 1*s.* 4*d.* to 2*s.* 6*d.* per cubic yd. largely dependent on the distance the material had to be conveyed. Some work has been carried out departmentally, including all establishment and capital charges, at a figure as low as 7½*d.* per cubic yd. This was for a quantity of about one million cubic yards, and the distance conveyed was about 30 miles.

River Mersey.—At the bar and in the entrance channels of the Mersey nearly 15 million cubic yds. of sand were removed annually at a pre-war cost of ·6*d.* per cubic yd. exclusive of interest and depreciation on the plant.

Siam Irrigation Canals.—The following particulars of the working expenses of a 2½-cu. yd. dipper dredger, employed on the Siamese Irrigation Service, are given by Messrs. Lobnitz & Co.:—

'During the year 1920, working nine hours per day, the total quantity dredged was 312,130 cu. yds., measured in place, or an average of 26,010 cu. yds. per month. The best month in that year was October, with 43,700 cu. yds. at a total cost of 1·95 pence per cu. yd., and the average cost per cu. yd. for the year was 2·87 pence, including labour, fuel, supplies, repairs, and every expense except interest and depreciation. The fuel used was oil, and represented about half the total operating cost. The quantity used was about one ton per day.

'While larger outputs have been made for short periods and under more favourable conditions, this record is notable chiefly for steady running for a long period without appreciable delays or expense on account of the machinery, and this in a tropical country remote from base of supplies. The cost of repairs was 4·3 per cent. of the total cost, and consisted mainly in the replacement of some wire ropes.'

SUBAQUEOUS ROCK REMOVAL.

The removal of hard rock under water is generally effected by one or other of two means: (*a*) by drilling and blasting; and (*b*) by the use of the chisel or rock breaker. In both cases a dredger is subsequently required for the purpose of clearing the débris from the site.

Drilling and Blasting.

Drilling and Blasting.—The first is the older method and remains still a most effective means of dealing with rock of adamantine hardness in huge solid masses, such, for instance, as reefs of granite and other igneous rock, and for the harder varieties of limestone.

The holes are drilled by suitable plant at distances apart dependent upon the nature of the rock and the quantity to be removed. In very extensive operations chambers may be formed for the reception of powerful charges.

Two classes of drill are generally available for boring purposes: (*a*) diamond drills and (*b*) jumper drills. The former are hollow rods, fitted with a head or crown of diamonds, costing from 50*l.* to 60*l.*, and driven at from 200 to 300 revolutions per minute. The latter are bars or shafts of steel, furnished with bits, preferably of circular form, which are worked by percussion at the rate of from 20 to 30 blows per minute.

The blasting material is usually dynamite, or any of the numerous compounds of nitro-glycerine to be found on the market.

The following are brief notes on the methods employed in several instances.

Blyth Harbour.—The rock at Blyth harbour is sandstone of the hardness of basalt in places, and the work was done by six drills lifted by steam power and guided by hand. The distance between the shot-holes was 5 ft. in one direction and 6 ft. 2 ins. in the other. The blasting material, bellite, was lowered in canisters through the drilling tubes and fired by fuses and detonators, the holes being tamped with small gravel. The cost of drilling and blasting came to 3*s.* per cubic yd. of rock *in situ*, adding to which 2*s.* 6*d.*, the cost of dredging, and 8·2*d.* for interest and depreciation on the dredger, the total amounts to 6*s.* 2·2*d.* per cubic yd. The average quantity of rock drilled and blasted per week by one barge was 488 cubic yards. The system was afterwards abandoned in favour of the rock-cutter.

Black Rock Harbour, Buffalo, U.S.A.—Here the rock formation is a very hard limestone containing veins of flint. The blasting material was dynamite and, for a quantity of 14,450 cubic yds., the holes were drilled to an average depth of 9 ft. 9 ins. The cost of drilling and blasting only, including an allowance for interest and depreciation of 2 per cent. per month on 8,000*l.* (the value of the plant), came to 2*s.* per cubic yd. On the other hand, a smaller quantity of 333 cubic yds. with holes drilled only to 3 ft. 6 ins. deep cost 23*s.* 2*d.* per cubic yd.

The drill boat employed on this work was a steel hull, 137 ft. by 33 ft., divided into 20 water-tight compartments. It was equipped with five drill frames located along one of the gunwales each with a travel of 25 ft. on longitudinal tracks. Each frame was fitted with an Ingersoll-Rand drill 2½ ins. in diameter, with 4-in. bits, having a vertical range of 21 ft. without changing the drill bars. Each frame was also provided with an engine for hoisting the drills, two davits for handling drill steels and charging pipes and a pipe which was driven, whenever required, through loose material to the rock to prevent the drill holes from clogging. A 250 h.p. boiler supplied steam to the drills, spud engines and capstans.

Detroit River.—On three sections of the Detroit River, where the blasting material was dynamite and the holes ranged from 5 ft. to 8 ft. in average depth, the total cost is stated to have been 3*s.* 4*d.*, 4*s.* 4*d.*, and 4*s.* 1*d.* per cubic yd., respectively, of useful material, or about half the rates for the whole quantity removed. The holes were spaced 5 ft. apart, and the total number drilled was 94,691 at a cost of about 52,000*l.* It is not apparent that this figure includes any allowance for interest and depreciation.

Fremantle Harbour, Western Australia.—On account of the shallowness of the water, the work of drilling at Fremantle Harbour could be carried on from light wooden stages resting on four-footed trestles. In a couple of days it was possible to erect 20,000 square ft. of this staging, which carried 120 to 160 men drilling with regularity in 20 ft. or more of water. The holes were from 8 ft. to 12 ft. apart, and the charges consisted of 12 to 15 lbs. of dynamite or gelignite. One ton of explosive accounted for 5,600 cubic yds. of rock blasted. The cost of drilling and blasting 1,503,099 cubic yds. was 238,345*l.*, equivalent to 3*s.* 2*d.* per cubic yd.

Rock Breakers or Chisels.

Rock breakers, or chisels, are steel rams weighing from 15 to 20 tons, with pointed ends of hard chrome steel which are detachable for renewal. The appliance is suspended from a frame, or tripod, mounted on a barge, and is worked by a winch. A drop of from 6 ft. to 10 ft. is generally sufficient to produce disintegration. Blows can be repeated with advantage until a depth of 3 ft. is reached, with holes spaced about 3 ft. to 4 ft. apart (about eight blows will give the required penetration), when it becomes desirable to dredge the broken material before proceeding further. A net depth of 2½ ft. over the site will probably thereby be obtained. It is found that the average result in hard rock is 2 cubic ft. per blow and that about 150 blows can be given per hour. This is equivalent in uninterrupted working to about 10 cubic yds. per hour for a single cutter machine; about 50 per cent. more will be achieved by a double cutter. In moderately hard rock the output will be greater, as about 250 to 300 blows can be given per minute. About 200 cubic yds. may be reckoned a good day's work.

There are several types of cutter, but perhaps the Lobnitz rockbreaker is that which is best known. The following are some instances of its employment. It may be added that some of the latest examples of this type of cutter have been fitted with an under-water sleeve, to afford more accurate guidance for the ram or chisel.

Suez Canal.—On the Suez Canal, where the rock consisted of limestone, calcareous agglomerate and tufa, gypsum and alabaster, 132 blows were delivered per hour of effective working, or 8 blows per hour of whole time, allowing for interruptions from passing ships and stoppages for repairs. The average thickness of rock shattered was 2 ft. 7½ ins., and each cubic yd. of rock required a mean of 5·4 blows. The cost, exclusive of dredging but covering everything else except general charges, varied from 2¼*d.* to 7*s.* 6½*d.* per cubic yd.

Blyth Harbour.—At Blyth in hard sandstone of the coal measures, a ram of 15 tons weight, falling through a distance of 8 ft., penetrated the rock to a depth of 3 ft. on an average of 8 or 9 blows. The holes were spaced 4½ ft. apart. The plant comprised two Lobnitz rock-breakers, each consisting of a steel barge carrying sheer legs, from which the rams, 40 ft. to 50 ft. long and 17 ins. to 19 ins. diameter, were suspended. The cost of one rockbreaker was about 6,800*l.* The quantity broken per week by a single machine working night and day was 908 cubic yds., at a cost (including wages, coal, stores, repairs and insurance) of 46*l.* 11*s.* 3*d.*, equivalent to 12·3*d.* per cubic yd. Adding 6¼ per cent. for interest and depreciation on plant, the total cost was 14·5*d.* per cubic yd. The cost of subsequently dredging the loose material (including capital charges) was 2*s.* 9·1*d.* per cubic yd., making 3*s.* 11·6*d.* per cubic yd. in all.

Black Rock Harbour, Buffalo, U.S.A.—The cost of working two Lobnitz machines at Black Rock Harbour in hard limestone rock was 2*s.* 9½*d.* per cubic yd. for a quantity of 52,500 cubic yds. This does not cover the cost of dredging.

Panama Canal.—On the Panama Canal, a Lobnitz cutter worked mounted on a barge 100 ft. long by 28 ft. beam by 8 ft. deep. The extreme variation in the tides necessitated the use of 3 rams, weighing 15, 16 and 19½ tons respectively. The holes were spaced 4 ft. apart, and 3 ft. of penetration was made in each case. From records during 1910–11 the work done was an average of 16·2 cubic yds. per hour of actual working time, or 11 cubic yds. per hour of total time, at an average cost of 3*s.* 4*d.* per cubic yd.

Value of the method of Drilling and Blasting as Compared with the use of Rock Breaker.—While drilling and blasting is most commonly adopted for hard rock in large masses, it does not necessarily follow that the cutter always gives better results in soft rock. In some cases it is found that the cutter has a tendency to stick in the hole which it makes, and for that reason the extent of penetration should be carefully limited. On the other hand, the cutter offers less interruption to the passage of ships close to the area of operations, and it can be used in positions where blasting is inadmissible. Moreover, the rock is broken to a more uniform and more convenient size, which facilitates the action of dredging. The cost of the work done by the cutter is generally, though not invariably, less than the cost by the alternative method.

CHANNEL DEMARCATION.

Entrance channels to ports are outlined by buoys and important changes of direction are also indicated by beacons and lightships.

Uniform System of Buoyage.

The general Lighthouse Authorities of the United Kingdom have adopted the following uniform system of buoyage.

Conical Buoys (those with pointed tops) denote the starboard hand, or that side which would be on the right hand of a mariner, either going with the main stream of flood tide, or entering a harbour, river or estuary from seaward.

Can Buoys (those with flat tops) denote the port hand, being the left-hand side of the mariner under the circumstances described.

Spherical Buoys, with domed tops, mark the ends of middle grounds.

Pillar Buoys, having a tall central structure on a broad base, mark special positions.

Colour.—Starboard-hand buoys are always to be painted in one colour only; port-hand buoys are to be painted another characteristic colour, either single or particolour. Spherical buoys are to be distinguished by white horizontal stripes. Wreck buoys are to be coloured green with the word 'wreck' in white letters across.

Types of Buoys.

Buoy Construction.—Buoys are generally hollow structures of steel or iron plating, at least ¼ in thick. They should be constructed in two watertight sections to prevent sinking in case of penetration of one part.

The size and weight of buoys is as follows:—

		Diam. ft.	Weight. tons.
Day Mark Buoys	First class	12	4
	Second class	10	2½
	Third class	8	1¼
	Fourth class	6	¾
	Fifth class	5	⅜
Gas Buoys		10	4

Gas buoys should be made of welded iron or mild steel, not riveted. Under high pressures the riveted joints tend to leak and are not satisfactory.

Buoy Moorings.—Mooring chains for first-class buoys are about 1¼ ins. diameter, and they are attached to sinkers weighing about 50 cwts. For second-class buoys the chains are usually 1¼ ins. diameter, and the sinkers weigh 40 cwts.

Bell Buoys are provided with a bell from 3 to 7 cwts. in weight struck under the action of the sea either by pendant clappers or by a set of balls rolling freely in horizontal grooves, or by a hammer actuated by carbonic acid gas.

Whistling Buoys emit a sound by means of air imprisoned in a long central tube during the period of rising in a swell and expelled through a whistle during the period of falling. The tube descends into the water to a considerable depth—about 20 ft.

Luminous Buoys.

Luminous Buoys are lighted by means of oil or gas: the former, petroleum; the latter, either oil gas, Blau gas, or acetylene. On account of the high pressure required for compact storage, coal gas is unsuitable for use as a naked flame, the luminosity of the gas being rapidly reduced by pressure. The heating power, however, remains almost intact, and with a mantle satisfactory incandescence is produced, though the brilliancy and luminous intensity are lower than those of the other agencies. The ratio of calorific value is approximately as follows:—Coal gas, 5; oil gas, 10; Blau gas and acetylene, 14.

The difficulty connected with the use of oil burners is the necessary attention to the wicks. In France carbonised wicks are employed, but they call for extreme nicety of adjustment. In this country the *Wigham* burner has an automatic contrivance which ensures a constant change of surface. The consumption of oil amounts to from 2 to 4 pints per day of 24 hours, according to the size of the lamp. Including oil and attendance, but not repairs, the approximate pre-war running cost of a 31-day buoy lamp works out at about ·13*d.* per hour, of which ·065*d.* is for oil. The prime cost of buoys equipped with the *Wigham* lamp is from about 200*l.* upwards.

Oil gas, as manufactured on the *Pintsch* system, is produced at a cost of about 60*s.* per 1,000 cubic feet, about 75 cubic feet of gas being obtained from one gallon of oil. The average burner of a fixed light consumes about ·75 cubic feet per hour. The gas is stored under pressure, generally of about 90 to 105 lbs. per sq in., but reaching up to 150 lbs. A reservoir of 380 cubic feet in a buoy of 10 ft. diameter, charged to 90 lbs. pressure, would hold a sufficient supply of gas for about four months.

Lenses are usually of 200 to 300 millimetres (8 to 12 ins.) diameter. The candle power of lanterns fitted with incandescent burners and lenses of 200 mm. diameter is about 220, and with 300 mm. lenses about 330.

Blau gas is derived from the decomposition at a lower temperature of the raw or residuary products from which ordinary oil gas is extracted, and is richer than the latter in heavy carbides of hydrogen. It is liquefied for storage in bottles. Before use, the gas requires to be expanded

in an intermediate receiver. The cost of production of Blau gas is considerably higher than that of oil gas, but the cost of transport is much less, and the increased heat of the flame gives an increase of 30 per cent. over oil gas to the intrinsic brilliancy of the mantle and the intensity of the lens.

Acetylene, a gaseous compound of hydrogen and carbon, is produced by the access of water to calcium carbide. In the case of buoys, the water is generally admitted to the chamber containing the carbide through a hole in the bottom, the generation of gas being regulated by the pressure arising from its formation. The system is wasteful of carbide, and only suitable for positions where the buoys can be periodically cleaned and recharged. The better principle, wherever feasible, is the inverse arrangement of the application of carbide to water.

From 1 lb. of commercial calcium carbide can be produced about 4½ cubic feet of acetylene, at a pre-war cost of about 1½*d.* for material only.

Acetylene gas produced as above is not chemically pure, and gives rise to deposit on the burners, but this difficulty can be overcome by the addition of a suitable purifier between the gas-generating chamber and the burner. Unattended lights working on this system will run for six months, or even a year, without recharging.

Dissolved Acetylene.—The compression of acetylene for storage purposes is generally illegal, on account of the liability of the gas, so stored, to explode. On the other hand, compressed acetylene in what is known as the dissolved form is perfectly safe, and cylinders of dissolved acetylene, prepared in accordance with official regulations, are classed by the Home Office as non-explosive.

The solvent commonly employed is acetone, which is a liquid hydro-carbon, possessing the property of absorbing about 25 times its own volume of acetylene at atmospheric pressure, and multiples of this to correspond with the number of atmospheres to which compression is carried.

The steel cylinders for the reception of the dissolved acetylene are first completely filled with a substance having a porosity of 80 per cent., which is then caused to absorb as much acetone as would occupy 40 per cent. of the volume of the cylinder. The actual gas capacity of the cylinder is thus 40 per cent. of 25, or 10 volumes per atmosphere of pressure.

Dissolved acetylene cylinders should not be discharged below the atmosphere gauge pressure, because the rate at which the acetone is carried off by the gas greatly increases as the pressure approaches zero. Acetone vapour has no detrimental effect upon the consumption of the gas in the burner. It is generally found necessary to make up the quantity of acetone, after five to ten refillings of the cylinder with acetylene.

Economies in the consumption of dissolved acetylene have been effected by the introduction of mechanism for emitting flashing or occulting lights invented by Mr. Gustav Dalen and others whereby a wide range of intermittent light signals can be produced automatically.

To the same scientist is attributable the *Sun-valve*, or, more correctly, the *Light-valve*, which is a mechanical device sensitive to light and actuated entirely by the alternation of daylight and darkness. It opens the gas supply at nightfall and closes it at daybreak with perfect regularity, resulting in a saving of some 25 to 40 per cent. of the gas, according to climate, as compared with a constantly burning light. The use of the instrument is generally restricted to shore lights, or lights of considerable magnitude.

Mr. Dalen has further produced complete automatic apparatus for mixing in correct and constant proportions the dissolved acetylene and air and for burning the compound in conjunction with incandescent mantles, either as a constant or intermittent light. This apparatus also by its nature, is most applicable to lights of considerable power, superior to those generally fitted to buoys.

As an instance of the cost of buoy illumination by dissolved acetylene may be mentioned nine light buoys in the entrance channel to the Port of Lido, Venice, which command a light range of 6 miles under conditions of average atmospheric clearness, and contain a supply of gas for a period of 110 days. The lenses are 300 mm. diameter, and the burner consumes 15 litres per hour. According to a statement of Sig. Carlo Duse in the 'Giornale del Genio Civile,' the annual pre-war cost per buoy, covering attendance and repairs and four charges of gas, each of 3 cylinders of 5 cubic metres, at 4*s.* per cubic metre, was 15*l.* 12*s.*

Further reference to the cost of acetylene lighting will be found on page 1559.

Lightships.

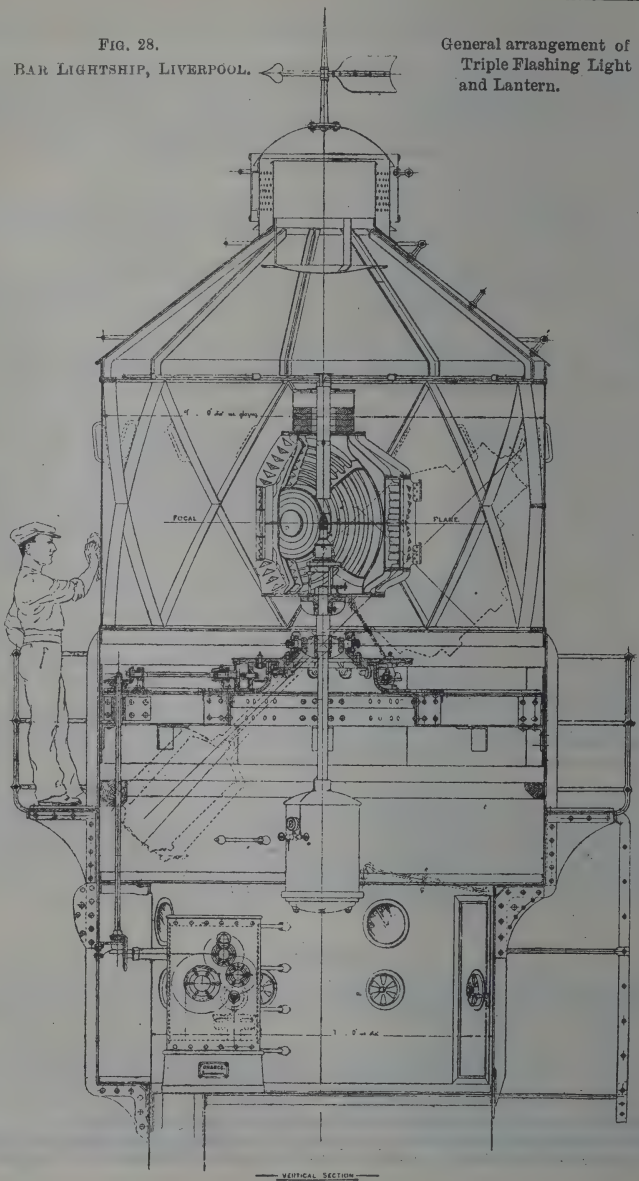
Lightships afford a more powerful light than luminous buoys, and the focal plane is at a much higher level—generally about 35 ft. above the water surface. They are, of course, more costly both in first outlay and maintenance, and are usually manned by a crew, though this is not essential in all cases.

A notable example of an attended lightship is the Bar at the entrance to the River Mersey. The illuminant in this vessel is petroleum with an incandescent mantle, and the lens is of small third order (750 mm. diameter). The whole optical apparatus is swung on gymbals, so that the beam emitted is kept practically horizontal. It is revolved by clockwork, and gives three powerful flashes, so that the whole installation resembles a floating lighthouse.

Small lightships, without constant attendance, are stationed at several places on the coast of this country and of France. A vessel of this type is about 40 ft. long, 12 ft. beam, and 8 ft.

FIG. 28.
BAR LIGHTSHIP, LIVERPOOL.

General arrangement of Triple Flashing Light and Lantern.



deep, fitted with a storeholder containing 2,500 cubic ft. of gas, which is sufficient to maintain a light for 3 months.

Larger vessels, with crews, range from 60 to 150 ft. in length, from 20 to 30 ft. in breadth and from 10 to 20 ft. in depth, the draught being from 7 to 10 ft.

Lenses vary from 500 mm. to 750 mm. in diameter and the candle-power from 2,000 to 250,000. Catoptric reflectors with a candle-power of 4,000 are used in the older types of light vessels.

LIGHTHOUSES.

The Eddystone Lighthouse.

The most recent type of foundations and general construction of lighthouses is well exemplified by the new Eddystone Lighthouse. In this structure the tendency of the curvilinear outline of Smeaton's and of other similar sea-towers that have succeeded it, to elevate the centre of force of each wave-stroke on the structure, induced Sir James Douglas to adopt a cylindrical base, from which base, at a level of 2½ feet above high-water spring-tides, the curved shaft of the tower commences. The difference in the rise of heavy seas on the two structures during stormy weather is remarkable. The cylindrical base has the further advantage of affording a convenient landing platform, thus adding considerably to the opportunities of relieving the lighthouse.

The base is 44 feet in diameter by 22 feet in height. The tower is a concave elliptic frustum, the generating curve having a semi-transverse axis of 173 feet, and a semi-conjugate axis of 37 feet. With the exception of the space occupied by the fresh-water tanks, the tower is solid for 25 ft. 6 ins. above high-water spring-tide level. At the top of the solid portion the wall is 8 ft. 6 ins. in thickness, diminishing to 2 ft. 3 ins. in the thinnest part of the service-room. All the stones are dovetailed both horizontally and vertically. The system consists in having a raised dovetailed band 3 inches in height on the top bed and on end joint of each stone. A corresponding dovetailed recess is cut in the bottom bed and end joint of the adjoining stones, with just sufficient clearance for the raised band to enter it freely in setting. From experiments made with blocks put together in this manner with Portland cement, it is found that the work is so homogeneous as to be as nearly as possible as strong as the solid granite.

Each stone of the foundation-courses (figs. 29, 30) is sunk to a depth of not less, at any part, than 1 foot below the surface of the surrounding rock, and is further secured by two Muntz metal bolts, 1½ inch in diameter, passing through the stone, and 9 inches into the rock below, the top and bottom of each bolt being fox-wedged.

The masonry consists of 2,171 stones, containing 62,133 cubic feet of granite, or 4,688 tons.

60	10·246	150	17·201	800	37·416
70	11·067	200	18·708	1,000	41·833

Optical Apparatus.

The essential part of a lighthouse is the optical apparatus, which is formed of glass lenses and reflecting prisms in order to concentrate the light from the burner in the required direction. The optical apparatus of a fixed light concentrates the rays in the vertical plane only, and sends out a disc of light which illuminates the horizon over the whole 360° or any less angle which may be required. That of a flashing light concentrates the rays in both the vertical and horizontal planes, and thus throws out a series of beams, the number varying with the character which the light is required to give. The whole apparatus is revolved, and by this means the beams sweep round the horizon and appear as flashes at definite intervals to the mariner.

Large lights are supported on a mercury float whereby friction of movement is reduced to a minimum; ball bearings are satisfactory for lights of the fourth order and upwards. The adoption of the mercury float and of the group flashing system, has revolutionised lighthouse practice. The former enables the largest type of optical apparatus the weight of which runs up to 10 tons, such as that illustrated in fig. 31 (p. 1558), to be rotated by the little finger only, and the latter has so greatly increased the distinctive characters which can be given to lights that there is now no danger of confusion between them.

It is usual to arrange the optical system so that the flashes have a minimum duration of ·2 seconds; it has been found that a shorter duration is not sufficient for the mariner to detect the flash. Fig. 31 also illustrates the lantern which protects the optical apparatus.

Sources of Lighthouse Illumination.

For the ordinary necessities of lighthouse illumination mineral oil is the most suitable and economical illuminant. The use of paraffin in the place of colza oil increases the luminous intensity of a four-wick burner by 10 per cent., and of a one-wick burner by 100 per cent.

Oil and gas lights, when shown through similar lenses, are equally affected by atmospheric variations. The electric light is absorbed more largely by haze and fog, but in all weathers and at all distances its penetration has proved superior.

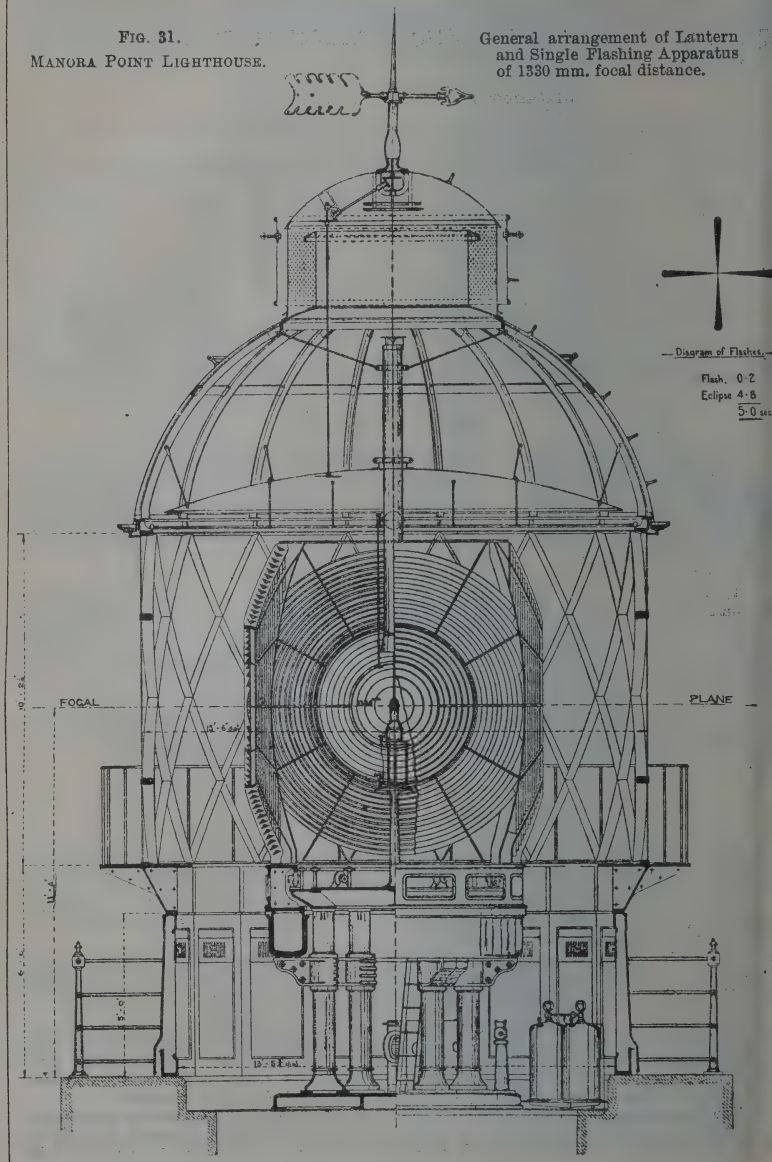
The luminary now in general use at lighthouses is the incandescent oil burner, to which paraffin oil is supplied under pressure, and is vaporised in a retort beneath the burner, being afterwards consumed in an incandescent mantle. The sizes of mantle usually employed vary from 35 mm. to 110 mm. in diameter with intensities up to 3,500 candles.

The latest burner of this type is the 'Hood' petroleum vapour burner designed by the late engineer-in-chief to the Trinity House, in which the mantle employed is of the autoform type, with an intrinsic brightness of 325 candles per sq. in. The burner is in four sizes, 35 mm., 50 mm., 75 mm., and 100 mm., with total intensities of 660, 1,150, 2,200, and 3,300 candles, and consumptions of 0·75, 1·25, 2·25, and 3·25 pints of oil per hour, respectively.

The substitution of incandescent oil burners for concentric wick burners has not only greatly augmented the intensity of the lights, but has resulted in a considerable economy in consumption, in addition to obviating excessive labour and expense of landing large quantities of oil

FIG. 31.
MANORA POINT LIGHTHOUSE.

General arrangement of Lantern and Single Flashing Apparatus of 1330 mm. focal distance.



at lighthouses, especially at rocks and isolated positions. The following may be cited as an example of the increased intensity and economy which are attained by the use of this luminary. At the Eddystone, which is a biform light having superimposed lenses and burners, the resultant beam with the former concentric six-wick burners was 79,250 candles, the consumption of oil being 2,500 gallons per annum; whilst with incandescent oil burners the resultant beam is nearly 600,000 candles and the consumption 1,200 gallons per annum.

For minor lighthouses and portlights (fig. 32, p. 1560) at the entrances to harbours, etc., the illuminant is sometimes a capillary wick lamp having one or more wicks, which can be left without attention for a single night. A distinctive character is given to such lights by means of revolving screens driven by a simple clockwork mechanism which will run for a night without rewinding; the screen occults the light at regular intervals. For the entrance to harbours where range is not a great consideration the light may be coloured red or green.

Many lights are now left unattended for long periods, and the illuminant is generally compressed oil-gas, stored in receivers, or acetylene gas, manufactured in generators on the spot or on the dissolved acetylene principle.

Dissolved Acetylene Light at Venice.

The following information respecting the cost of illumination by dissolved acetylene at the Lighthouse on the North-East breakwater of the Port of Lido, Venice, is extracted from a report by Sig. Carlo Duse in the 'Giornale del Genie Civile,' 1913.

The Lighthouse is fitted with a dioptric lens of 300 mm. diameter. The burner consists of three single elements aggregating 60 litres per hour capacity, equal to a white light, through the lens, of 800 Hefner candle-power, or 720 standard candle-power.

The light shown is a green flashing light with two flashes, each of 1½ seconds duration, the first followed by one second eclipse and the second by four seconds eclipse. The light is visible for a distance of nine miles, under conditions of average clearness. It is automatic and is controlled by a Dalen Sun-valve.

The gas magazine consists of 8 dissolved acetylene cylinders or accumulators, each of 5 cubic metres capacity. This supply suffices for an uninterrupted period of 115 days, during which no attention is given to the light.

The initial cost of the lighthouse was 2,960*l.* for the structure and 600*l.* for the light apparatus. A statement of the estimated annual working cost is as follows:—

	£	s.	d.
Three charges of gas, each of 10 cylinders of 5 cubic metres capacity at 4*s.* per cu. m.	30	0	0
Exchange of cylinders and carriage	10	10	0
Casual repairs, rectification and periodical visits	4	16	0
	£45	6	0

The dissolved acetylene was obtained from a local compressing station, but at the date of the report it was under contemplation to establish a compressing station as part of the lighting undertaking in the expectation that the price of the gas would be reduced to 2*s.* per cubic metre.

Relative Absorptive Powers of Coloured Glass.

With the best red glass the ratio between the powers of the red and white lights is as 2 to 5.

When colour is necessary in fixed dioptric apparatus the coloured beam can be strengthened by condensing prisms, whilst for revolving dioptric apparatus the red and white can be approximately equalised by giving to the red beam a greater breadth and a special arrangement of the lens and prisms.

A pink is better than a red tint.

During thick weather red lights are not so much absorbed by the atmosphere as white.

Glazing.

The glass of lighthouses is usually ⅜ in. thick, except in peculiarly exposed situations, where it is ½ inch.

The astragals are 1 in. in section, of gun-metal, having a tensile strength of 33,000 lbs. per square inch.

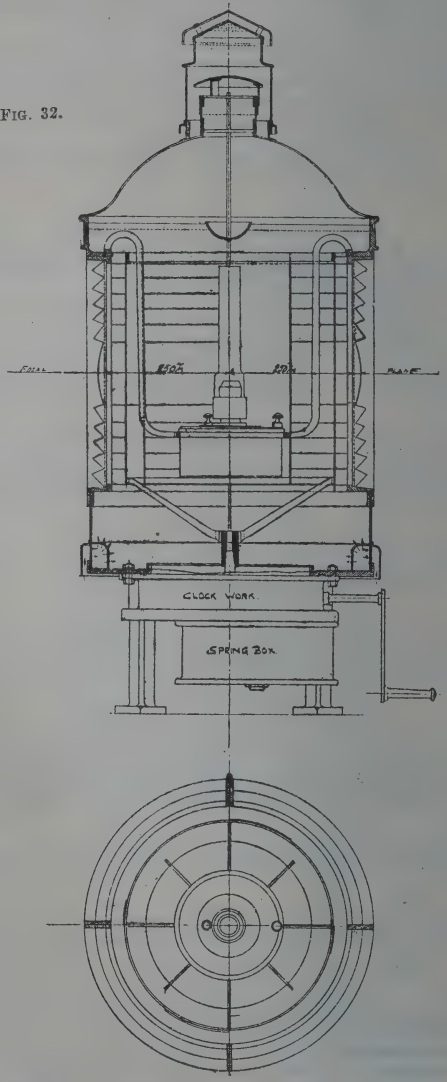
Diagonal astragals do not intercept light in any one azimuth throughout their whole height, and they secure great rigidity and strength.

Ordinary first-order lanterns are 12 ft. in diameter and 10 ft. high in the glazing.

The Bishop Lighthouse has a lantern of 14 ft. diameter and 15 ft. high; Fair Island, 14 ft. diameter, 6 ft. 2 ins. high; Tory Island, 14 ft. 9 ins. diameter, 18 ft. high; Sule Skerry, 16 ft. diameter, 12 ft. 2 ins. high.

FOURTH ORDER OCCULTING PORTLIGHT.

FIG. 32.



Lightning Conductors.

These should be of ¾-in. best quality copper rod, carried 18 ins. above highest part of ventilator of lantern, and then terminated in three branches with platinum caps or platinum wire No. 8 B.W.G., screwed and soldered into the rod; the latter should be put into metallic connection with all internal masses of metal. The earth connections should be made by copper plates, 20 ins. by 12 ins., and ⅛ in. thick. Conductors should be periodically inspected.

Audible Signals.

The types of sound signals in use by the Trinity House are:—(1) aerial and submarine bells; (2) explosive signals; (3) reeds; (4) sirens; and (5) diaphones.

Of the first of these, **Aerial Bells**, actuated by the motion of the ship or buoy carrying them, are well known, but a new method of operating the striking mechanism has been recently installed at the unattended lighthouse on the Menai Straits and on the Lune Deep unattended gas boat.

The bells in each case weigh 10 cwt. The striking hammer is interior to the bell, and the striking action is performed by the admission of carbonic acid gas under pressure to the underside of a diaphragm which actuates the hammer striking the bell; the gas is then exhausted into the atmosphere and the hammer returns to a vertical position preparatory to another impulse. A battery of 24 cylinders of CO_2 gas is capable of maintaining a bell signal with a character of 1 stroke every 15 seconds for twelve months without re-charging.

Submarine Bells are of several types, one of which is operated by the motion of the floating body to which it is attached, and another by a regulated pressure of air or CO_2 gas, in order to impart a definite character to the signal.

The bells used on Trinity House light-vessels are suspended outboard from a davit, and when lowered are approximately 18 feet below the water line. They are operated by compressed air at a pressure of 15 lbs. per sq. in., which is led from a receiver on board the vessel through a rubber pipe to the striking mechanism actuating the bell hammer.

The third type of submarine bell, of which only one exists in the Trinity House Service, is electrically operated, and is laid in twenty-four fathoms of water—three-quarters of a mile off South Stack lighthouse in North Wales. The bell is fixed to a tripod 21 ft. high, and is connected by a 4-core cable with the engine-room at the lighthouse, where a current of 3 amperes at a pressure of 200 volts is generated by a Crompton motor; this is pulley-driven by the 5-h.p. oil engines which simultaneously work the air-compressing plant for the reed fog signal.

Telephone lines connect a microphone in the electro-magnet casing and a receiver in the engine-house, so that the keeper on watch can ascertain if the bell is sounding properly or not.

Explosive Signals consist of the firing of a gun, explosion of acetylene gas, or the detonation of gun-cotton charges from a rising and falling jib on the lantern roof, of which last system there are seven instances in the Trinity House service, possessing a special feature in the safety gear by which premature firing is obviated while the jib is in its lowered position for loading. This is effected by leading the wires from the battery switch on the lantern pedestal to terminals outside the lantern roof, and fixing to the trunnion of the jib spring contact strips which make and break contact between the battery and detonator leads, when the jib is raised and lowered; by this means, after the jib has been moved through a small angle out of the vertical, no firing of the charge is possible until it is again raised, and consequently no danger to the keeper, or damage to the lantern glazing, can accrue.

Explosive signals are now fired by wireless. A recent representative installation on the Clyde consists of a gun which is charged with an admixture of air and acetylene gas and is fitted with wireless receiving apparatus. A synchronous transmitting set is installed on a pier 1½ miles distant. When fog is observed, the transmitting installation is put into operation and the impulses sent out are received on the apparatus attached to the fog signal gun. The synchronising arrangement renders the installations immune from atmospherics and interference from other wireless waves.

The three remaining and most important types of sound signals will be dealt with conjointly, as each is operated by compressed air, and the only difference lies in the type of instrument producing the sound.

Reed Signals are, as a rule, sounded at a pressure of 15 lbs. per sq. in. from a vertically fixed conical horn with a bent top. The reed tongues are of steel 3 ins. long by ⅛ in. wide, and are tuned to give a note of about 450 vibrations per second, with a consumption of ⅔ cu. ft. of free air per second of blast.

Manual reed signals are sounded at 5 lbs. per sq. in., and the character is produced by a hand-operated valve.

Siren Signals are sounded at a pressure of 25 lbs. per sq. in. from horizontal tapered elliptical trumpets, and from vertical conical horns with bent tops. In all cases, except at Trevose Head Lighthouse, the siren is automatic and produces a note of about 187 vibrations per second with a consumption of 11 cu. ft. of free air per second of blast.

The siren at Trevose Head is 12 ins. in diameter, with only one port to the trumpet, and is driven by a small Brotherhood air motor. In this instance there is only one trumpet, which is a specially constructed Rayleigh elliptical steel horn.

The modern form of sound signal is the 'Diaphone,' such as that installed by the Trinity House service at Caskets Lighthouse, off Alderney, one of the Channel Islands, and elsewhere. They are sounded at a pressure of 30 lbs. per sq. in. and have a consumption up to 45 cu. ft. of free air per second of blast.

Audibility.

Under favourable conditions a steam siren may be heard at a distance of 14 miles, but sometimes the range does not exceed 2 miles.

A compressed-air siren (0·125 metre in diameter) has been heard at a distance of 13 miles but the range is sometimes as low as 1·75 mile. A small-sized siren (0·042 metre diameter) cannot be heard at a greater distance than 1·85 mile under favourable conditions.

A 4-oz. charge of cotton powder can be heard under favourable conditions at a distance of 20 miles, and under unfavourable conditions at a distance of 2½ miles.

The distance traversed by the sound from submarine bells has reached 15 miles, but 1 to 2 miles is a serviceable distance.

Modern Navigational Devices.

See *The Engineer*, November 7, 1924, Abstract of lecture by F. E. Smith, F.R.S. (Director of Scientific Research, Admiralty), before the Royal Institution, February 29, 1924. Relates to navigational devices based on the acoustic and electro-magnetic properties of sea water and the directiveness of radio-telegraphy.

DIVING.

Forms and Limitations.—Diving is practised in three forms—either naturally, without any extraneous supply of air during submersion, or artificially, under pneumatic pressure (*a*) with a diving dress or (*b*) with a diving bell. The first is the most primitive method and, though still in vogue among natives in Eastern seas, is bound to be intermittent, in spells of short duration, as it causes great physical strain, leading not merely to acute discomfort, but at times to bleeding at the nose, mouth, and ears. When practised with the aid of pneumatic apparatus, the period of submersion may be greatly prolonged. The only practical limitation is in regard to depth. For every 33 ft. below water, the pressure on the lungs is increased by 1 atmosphere (14·7 lbs. per sq. in.) Thus, at 50 ft. below the surface the pressure is 22½ lbs. in excess of atmospheric pressure; at 100 ft it is 44½ lbs., and so on. Such pressures, though considerable, may be sustained with impunity, and even a depth of 150 ft. may be reached without ill effects. But greater depths necessitate considerable powers of resistance and are attended with risk. Until recently the maximum depth to which any diver had descended, as recorded by authentic testimony, was 210 ft., at which depth the pressure was rather more than 7 atmospheres absolute. But in August 1924 some trials, made in Walchensee Lake, Bavaria, with a deep-sea diving outfit prepared by a German firm, are reported to have indicated the possibility of executing work at much greater depths than this. One diver went to a depth of 140 metres. The apparatus proved water and pressure tight, and all turning joints could be moved. He could see for half a metre only. Then another diver went 160 metres below the surface of the water, but at that depth there was absolute darkness. He could walk on the bed of the lake without difficulty. Hoisting from this depth to the surface took only 4½ minutes. On the following day, work, such as fastening a shackle to a sunk piece, was done at a depth of 110 metres. At 160 metres, the maximum depth, the pressure amounts to 225 lb. per sq. in. Harbour work does not generally entail diving in water of more than 10 fathoms (60 ft.).

Caisson Disease.—After immersion under pressure the blood becomes more or less saturated with nitrogen in dissolved form, and when the pressure is relaxed the surplus gas is given off—if too rapidly, bubbles of gas form in the circulatory system, resulting in pains ('pins and needles'), asphyxiation, paralysis, and death, according to the intensity. To these symptoms is given the name of *Caisson Disease*, from its association with work carried on in caissons under pneumatic pressure. It is the most formidable antagonist of the diver, prostrating even the most powerful and robust. Fortunately the malady does not manifest itself at all under moderate pressures, viz., those less than 2 atmospheres absolute. For depths exceeding 35 or 40 ft., it is

necessary to use circumspection during the process of decompression, i.e., the ascent to the surface should be made slowly, with stoppages at intervals. By this means the evil effects can be neutralised.

The following table indicates the ordinary time limits in deep water, stoppages in ascent, and approximate air supply, in accordance with Prof. Haldane's recommendations and the latest British Admiralty practice:—

TABLE.

Depth.		Pressure, Lbs. per Sq. In.	Time under Water from Surface to Beginning of Ascent.	Stoppages in Minutes at different Depths.			Total Time of Ascent, Minutes.	No. of Cylinders needed.	Revolutions of Pump per min.
Feet.	Fathoms.			30 ft.	20 ft.	10 ft.			
0–36	0–6	0–16	No limit	—	—	—	0–1	1	15–20

			35 to 55 min.	5	10	15	32	2	30

Diving Bells.

As an alternative to the diving dress, the diving bell, a chamber constructed of mild steel plating, carefully riveted and securely caulked so as to be perfectly watertight, may be suspended over the place of operation and lowered or raised as required. The scope of movement by workers is naturally restricted to the area occupied by the bell, which may be 20 ft. by 10 ft. or thereabouts. Some submarine caissons are of much greater dimensions, but they are not diving bells in the true sense of the word. The interior is fitted with seats and footrests for the occupants, who may perhaps number a dozen. The bell is ballasted with cast-iron kentledge to enable it to sink without risk of overturning.

NOTE.

In the process of raising the United States submarine S 51, attempts were made to tunnel through the clay beneath her, by means of water jets, 2½ ins. in diameter, at a pressure of 50 lbs. per square inch, but the divers were unable to hold the jets against the reaction. To counteract this reaction, the nozzle had behind it five other smaller holes directed backwards. The reaction of these jets counterbalanced that of the main jet, and the diver could comfortably control the nozzle when working at even 200 lbs. pressure.

Important Books on Port Operation

By BRYSSON CUNNINGHAM

D.Sc., B.E., M.Inst.C.E., F.R.S.E.

Consulting Engineer; Author of "Dock Engineering," "Harbour Engineering," "The Dock and Harbour Engineer's Reference Book," etc.; formerly Editor of "The Dock and Harbour Authority"; Lecturer on Waterways, Harbours and Docks in the University of London.

Cargo Handling at Ports

A systematic study of methods of shipping and discharging cargo as practised at the leading ports of Europe and North America, with a critical examination of their merits and defects. Contains a great amount of useful data collected by the Author during visits to British and foreign ports in the course of his investigations.

2nd Edition, Demy 8vo. 190 pages. 124 figures, including 56 full-page half-tone plates and 5 folding plates. Price 13/6 net.

Port Administration & Operation

A Review of Systems of Management in vogue in various Countries.

Demy 8vo. 191 pages. 27 figures, including 18 half-tone plates. Price, 13/6 net.

CHAPMAN & HALL, LTD.

11 HENRIETTA STREET, STRAND, LONDON, W.C. 2

Port Economics

An elementary Study of Port Affairs specially intended as an introductory text book for students.

Demy 8vo. 134 pages, with 23 illustrations including 14 full-page half-tone plates and one folding plan. Price 6/- net.

SIR ISAAC PITMAN & SONS, LTD.

PARKER STREET, KINGSWAY, LONDON, W.C. 2

NAVIGABLE WATERWAYS.

Classification.

(1) **Natural Channels**, i.e., those rivers, or portions of rivers, including estuaries, the normal flow of which is not interfered with by artificial works;

(2) **Canalised Rivers**, frequently called 'Navigations,' the flow of which is more or less under artificial control and

(3) **Canals**, proper, entirely artificial in conception and construction.

The distinction between the three classes is fundamental and important. In the case of the natural channel, improvement works are limited to a rectification of the bed, and no attempt is made to control or augment the natural flow of water, which, being derived from the drainage of the basin, is normally sufficient for purposes of navigation, within the limits of the channel capacity. The canalised portions of rivers consist of sections in which the natural flow is conserved and controlled, as in the manner of a canal, but generally without extraneous sources of water supply. Canals, being works of an entirely artificial character, have to be fed with supplies obtained by the interception of streams, or from other external sources, frequently necessitating pumping and reservoir storage.

Internal Waterways in the United Kingdom.

According to the Report of the Royal Canal Commission, issued in 1909, the total mileage of Canals and Navigations in use in the United Kingdom is about 4,670. Of this total, about 1,639 miles lie in England and Wales, 183 in Scotland, and 848 in Ireland. The length of canals in existence in England and Wales is given as 1,927½ miles, and of navigations, 1,312½ miles. There are 812½ miles of open river and estuary.

IMPEDIMENTS TO NAVIGATION OF RIVERS.

In the seaward section the most pronounced disability, where it exists, is the bar. For its removal a very efficient means, producing immediate amelioration, is dredging; but the effect in the majority of cases is merely temporary, and operations must be continuous if the improvement is to be maintained. Where bars are not in evidence, or not very pronounced, a river mouth is often encumbered by shoals, due either to detritus brought down by the river itself or to coastal erosion and drift. In this case also, dredging may be resorted to with immediate advantage.

For permanent benefit it is requisite to supplement this temporary expedient by training works of a scope and magnitude dependent on circumstances. Such works comprise longitudinal training walls, or embankments, and groynes, dykes, or jetties, to be alluded to later.

In the upper sections of rivers the principal difficulties encountered are irregularities in flow due to floods in rainy seasons and depletion of water in periods of drought, excessive current velocity, instability of channels and the formation of shoals. In low-lying lands, it is often necessary as a protection against inundation to raise the river banks with impervious material well supported from behind. Insufficiency of water may be met by the introduction of weirs, or the formation of storage reservoirs. The remedy for excessive and irregular currents lies in training works of a suitable character.

Velocity of Flow in Rivers.

The velocity of river flow varies very considerably, as will be seen from the following table. As regards navigation, currents exceeding three to four miles an hour or four and a half to six feet per second make a serious deduction from the speed of propulsion of vessels proceeding upstream and render control difficult in the case of small craft travelling downstream. See also par. on Horse Traction, page 1587.

River Seine at Meulan .	2·45 ft. per second.	River Rhine at Basle .	6·36 ft. per second
„ „ at Paris. .	4·00 „ „ „	„ Aar at Berne . .	7·50 „ „ „
„ Thames at London Bridge . .	3·00 „ „ „	„ Durance, below Sisteron . . .	8·65 „ „ „
„ Tiber at Rome .	3·40 „ „ „	„ Maranon, S. America	13·00 „ „ „

Velocity Observations are taken by means of (*a*) Floats, (*b*) Current Meters, and (*c*) Pressure Tubes.

Floats.—For surface velocities an orange is excellent, floating almost wholly immersed. In the winter season, fragments of ice give similarly good results. The topmost layers of water, however, are frequently affected by the wind. To obviate this the float should extend some distance below the surface. A corked bottle, weighted at the bottom, has proved satisfactory for the purpose. Tube floats are also employed, consisting of tin cylinders about 1 in. diameter weighted so as to maintain perpendicularity, and leave two or three inches projecting above the surface. Double floats are sometimes used, consisting of a small surface float connected by means of a cord to a float of larger bulk below. In Mississippi experiments, the lower floats were kegs 9 ins. high and 6 ins. diameter, or 12 ins. high and 8 ins. diameter, according as depth was less or greater than 5 ft. They were without top or bottom, and ballasted with lead. The connecting cords were $\frac{3}{16}$ in. to $\frac{1}{2}$ in. diameter. The upper float was of light pine, $5\frac{1}{2}$ ins. square by $\frac{1}{4}$ in. thick, or of hollow tin, $5\frac{1}{2}$ ins. by $1\frac{1}{2}$ in.

Current Meters.—These record velocity by means of the revolution of a screw, being calibrated by drawing through still water at various speeds. Price current meter, used by United States Geological Survey, consists of six cups attached to a vertical shaft, which revolves on conical hardened steel point when immersed in moving water. Meter measurements can be made from a bridge, from a cable and car specially installed for the purpose, from boats or by wading. Current meters are affected by friction, and are not very suitable for low velocities; in fact, in feeble currents they cease to act.

Pressure Tubes.—Pitot tubes, which are ⌊ shaped with the lower horizontal limb pointing upstream, record the velocity by the height to which the water in the tube is forced above surface level by the pressure of the current. Darcy's adaptation consists of two tubes in communication, enabling the differential reading to be taken more accurately and eliminating the effect of ripples and oscillations. The apparatus gives good results in small channels with currents of fair velocity, but it is not suitable for large rivers or for very low rates of flow.

Position of Maximum Velocity may be taken generally at or about surface level, but is not infrequently below. The view is generally held that the velocity varies as the abscissa

of a parabola, whose axis is parallel to the surface. The equation for the parabola in the case of the Mississippi was found to be

$$v = -0{\cdot}79222\ d^2 + 3{\cdot}2611$$

where,
v = velocity in feet per second and d is distance from axis in fractional parts of whole depth considered as a unit.

Mean Velocity.—The position of mean velocity has been found by repeated experiments in U.S. Geological Survey to be located at about 0·6 of the total depth. The mean of velocities obtained at 0·2 and 0·8 of the depth gave the mean velocity of the stream very accurately.

In ordinary cases the least, mean and maximum velocities may be taken in the ratio 3 : 4 : 5. In very slow currents they are nearly as 2 : 3 : 4.

Prony's Formula:

$$\frac{\text{Mean velocity}}{\text{Maximum velocity}} = \frac{\text{Maximum velocity} + 7{\cdot}71 \text{ ft. per sec.}}{\text{Maximum velocity} + 10{\cdot}28 \text{ ft. per sec.}}$$

Computed Velocity.—A great number of formulæ have been published connecting the velocity with the hydraulic mean radius (R) = $\frac{\text{area of stream}}{\text{wetted perimeter}}$, and the sine of slope (S) = $\frac{\text{fall in level}}{\text{length of channel}}$. Most of these expressions can be reduced to the form

$$v = c\sqrt{RS},$$

where c is a coefficient varying with the class and nature of the channel, as well as with the personality of the observer. Some of the coefficients are very complicated, and the values are variable to a considerable degree. Mr. A. A. Barnes ('Hydraulic Flow Reviewed,' 1916) proposes to modify the powers of R and S so as to admit of a coefficient of constant value. His expression is

$$v = 58{\cdot}4\ R^{\cdot 694} S^{\cdot 496}$$

or, approximately,

$$v = 60\ R^{\cdot 7}\ S^{\cdot 5}$$

In nineteen observations with ranges in width of stream from ·26 ft. to 2,598 ft., in depth from ·19 ft. to 69 ft., in hydraulic mean radius from ·0786 ft. to 53·6 ft., and in slope from 1¾ to 241·2 ft. per mile, velocities of from 1 to 7½ ft. per second were computed and found to agree, within 1 per cent., with actual observation.

In the course of investigations made during three years in connection with the regulation of the Whangpoo and Yangtse Rivers, Dr. Herbert Chatley found that in fairly straight and uniformly sectioned reaches when the flow is steady the above exponential form $v = cR^{\cdot 7}\ S^{\cdot 5}$ gave consistent results. But when the flow was unsteady he found it more satisfactory to take the expression

$$v = cR^{\cdot 7}\left(S - \frac{a}{g}\right)^{\cdot 5}$$

where a is the acceleration. In other words, the effective slope was equal to the algebraic difference between the actual slope and an 'acceleration' slope determined by the ratio of the actual mean acceleration of the water to the gravitational acceleration.

Critical Velocities.—The following is a statement founded on the researches of Dubuat and Beardmore of velocities at which various materials in a river bed commence to be eroded:

Soft clay	3 ins. per second.	Rounded pebbles, 1 in. diam.	2 ft. per second
Fine sand	6 ,, ,, ,,	Rough gravel	2¼ ,, ,, ,,
Coarse sand and pea gravel	9 ,, ,, ,,	Pebbles 1¼ in. ,,	3¼ ,, ,, ,,
Gravel as large as French beans	12 ,, ,, ,,	Heavy shingle	4 ,, ,, ,,

TREATMENT FOR EROSION.

Protection of River Banks.—Water plants form a very efficient natural protection and they assist in retarding the current—sometimes not an unmixed advantage.

Earthen banks of a soft and erodable character may be artificially protected, where stone is procurable, by rubble pitching, laid at a slope of $1\frac{1}{2}$ or 2 to 1, from 8 to 12 ins. thick at the top and increasing in thickness downwards at the rate of 3 ins. per yard. The foot of the slope should be adequately secured to some firm abutment, such as piling, otherwise the pitching may be undermined and, in that case, it will subside.

Where stone is not procurable, fascine aprons or mattresses, formed of brushwood, may be utilised. These are bundles of branches and twigs (usually willow) from 9 to 12 ins. in diameter about 12 ft. long and bound with tarred rope at intervals of 4 ft. or so, laid side by side and tied together so as to produce a surface covering of the desired extent. The 'fascines,' as they are termed, should be secured by stakes or short piles to the bank upon which they are deposited.

A plantation of small willows above water level is useful in counteracting the more deleterious effects of floods.

Mississippi River Bank Protection.—The banks of the Lower Mississippi are protected where necessary from erosion below water surface level by means of brushwood mattresses loaded with stone. The portion of the bank above surface level is protected by a covering of stone only, 10 ins. thick, laid to a suitable slope.

The mattresses were deposited from a single barge, or from a couple of barges, placed end to end, so that the combined length of the barges exceeded the width of the mattress. The ordinary size for mattresses was 800 ft. by 250 ft., but some mattresses were 1,000 ft. long by 300 ft. wide. 'The mattresses are constructed on the mattress-barge by laying parallel to the shore, and 8 or 10 ft. apart, a series of poles, whose aggregate width equals nearly that of the proposed mattress. These poles are small trees from 3 ins. to 6 ins. diameter at the butt, and 25 ft. to 30 ft. long. Smaller poles are then placed at right angles to the larger series, so as to pass alternately beneath and above the successive larger poles, as in basket-work. These smaller poles when forced into close contact with each other and with the other series, form a tolerably compact web or mattress. When so many of the small poles have been added that they approach the ends of the larger series, whose poles are parallel to the shore, these larger poles are each continued by having another large pole spliced to it, and so on, for the length of the mattress. The brush in the mattress is fastened together frequently with iron wire and cross poles. The whole mattress is strengthened by wire cables about 20 ft. apart, and by $\frac{3}{4}$ in. to $\frac{5}{8}$ in. wire ropes running longitudinally the whole length of the mattress. Transverse cables of wire, about 16 ft. apart, also strengthen the mattress; and transverse wire ropes in addition are sometimes used.'

'As each mattress was woven it was allowed to be floated down stream off the barge by the current, and when a sufficient length had been accomplished it was loaded with stone and sunk, the upper end being sunk first. The customary under-water slope did not exceed 1 in 3, and the depth of the outer edge often ranged from 60 ft. to 100 ft. (*From Report by General C. B. Comstock, on Mississippi River Improvement, to Chicago International Congress*, 1893.)

Flexible mattresses of reinforced concrete are being experimented with on the Mississippi.

CHANNEL TRAINING WORKS.

The instability and eccentricity of channels is remedied by training works, comprising (*a*) projecting jetties and groynes, (*b*) longitudinal dykes and embankments, and (*c*) ground sills.

Groynes or Jetties project from the banks to the stream at right angles, or thereabouts (generally within 70° to 90°) to its course, and have the effect of reducing the channel and concentrating the scour of the current within certain bounds. The beneficial effect, however, is largely local, and, in the absence of restraint between the jetties, the stream tends to diffuse itself over a wider area, so that while the bed may be deepened and improved opposite the ends of the groynes it often becomes actually shallower in the intermediate spaces. To be effective groynes should be spaced apart not more than five times their own length, and this often renders them less economical than a system of longitudinal dyking, which, on the whole, will be found far more satisfactory and is often ultimately adopted. Groynes should, in fact, only be looked upon as of the nature of a temporary expedient. They may be formed of piling, fascine work or rubble.

Groynes on the River Waal.—These are so arranged as to point upstream with the axis of the groyne on the concave bank forming an angle of 80° with the projected channel, and that on the convex bank an angle of 70°. This system has been found favourable to the deposit of alluvium between the groynes.

The groynes themselves are formed of a core of sand extending to 11 ft. 6 ins. below ordinary low water. The core is covered with mattresses of fascine work, having a lateral slope of 6 to 4, surmounted by a layer of broken brick and rubble stone. The slope towards the river is 1 in 4. The width of the crown of the groynes is 11 ft. 6 ins., and their height along the boundary of the normal river bed 1 ft. 6 ins. above ordinary low water level, corresponding to about 1 ft. 6 ins. below mean water level.

It is stated that sand forms a satisfactory core if banked in large quantities at a time, and that no harmful results ensue from the slipping away of a certain amount during submergence. A few years after formation the groynes receive a protective covering of basalt.

The River Waal has a velocity varying between 2¼ and 3½ ft. per second. The discharge is about 21,000 cubic ft. per second at lowest water level, and 220,000 cubic ft. during highest floods. (*From Report by M. Baucke to Philadelphia Navigation Congress*, 1912.)

Longitudinal Dykes are walls or embankments of timber, stone, concrete, fascines, or other material built up so that the channel is rigidly confined within definite limits throughout the length treated. At the outlet of the Fen Rivers in the Wash, banks of fascine faggots and clay were constructed 22 ft. wide at the base, 17 ft. high, and 13 ft. wide at the top, at a cost of about 1*s.* 8*d.* per cubic yard. On the River Weser, stone and gravel embankments have been found preferable to fascines on the ground that the surface slopes may be rendered less steep than 45°, which is stated to be the limit for fascine work.

River Training Works at the Mouth of the Danube.—Operations for the improvement of the navigable channel at the Sulina mouth of the Danube have been in progress for more than half a century, under the direction of the European Commission of the Danube, an international body, constituted in 1856 by the Treaty of Paris.

There are three main arms, or branches, of the Danube delta, at its influx into the Black Sea. The Sulina arm, with the port of Sulina at its mouth, was chosen for treatment by reason of its greater depth and general use, despite the fact that its discharge was scarcely 10 per cent. of the total.

Rudimentary timber piers, consolidated by concrete mass-work and stone rubble, were constructed in the first instance, thus concentrating the outward current, and by the scour so occasioned, the depth across the bar of the river was increased from 9 ft. to 17 ft. rapidly; and subsequently more gradually to 20½ ft., at which figure it remained, naturally, for a period of 22 years until 1894, when dredging was commenced and a depth of 24 ft. obtained, necessitating, however, continuous maintenance work. In 1915 the depth of 24 ft. was lost and three dredgers proved incapable of re-establishing it. On account of the progressive advance of the delta, the action of natural forces, aided by artificial means, had become insufficient to cope with the deposit of alluvium, which, indeed, threatened to destroy serviceable access to the river for shipping.

In 1922 a prolongation of the piers or jetties was begun, and in 1925 was completed to a point of about 3,300 yds. from the Sulina Lighthouse, which is located at the port entrance. On July 25, 1925, the new channel, 200 ft. wide, was opened to traffic with a minimum depth of 20 ft., which within a month was increased to 23 ft. Deposit, however, continued to take place at the outer extremities of the piers, and a further prolongation is now in progress with the object of reaching deeper water for the pierheads.

Levees constitute a type of longitudinal dyke. They contract the river channel in its higher stages and protect the adjacent country from inundation. As used in American practice, they are generally banks of earth or spoil, well consolidated, with a central trench forming an impervious connection with the natural ground.

Channel Curves.—The natural tendency of river channels is to form a series of deep water pools on the concave sides of bends, with shoals at the intervening points where the current passes over from one side of the river to the other. A judicious system of training will maintain the natural sequence of these deep pools, at the same time suppressing any unduly sharp bends which might be awkward for navigation. Generally speaking, for vessels of 400 to 600 tons moving at a fair rate of speed a radius of 550 yards should be regarded as a minimum—at low speeds, 220 yards will suffice. The minimum for vessels of very small tonnage (say, 200 tons and under) may be as low as 66 to 88 yards.

Ground Sills are serviceable where there is excessive scour of the bed or undue restriction in width of channel. They have the effect of rendering the fall of the stream more uniform. In German practice they are set from 40 to 50 feet apart, and found to be better than continuous pitching or filling of the bed. They are laid across the river so that their highest levels at the bank are about 12 inches below the normal surface, and they slope downwards to the centre of the stream at an angle of about 1 in 40. On the Mississippi the ground sills consist of either rubble mounds or cribs filled with rubble, or, again, of brush mattresses and stone in alternate layers. Whatever form be adopted, the top should be finished off smoothly to prevent injury to passing vessels. Ground sills may be used where it is desired to raise the low water level or lengthen out a slope.

Storage Reservoirs.—For the augmentation of the flow in dry seasons storage reservoirs have been advocated, and in two instances—the Mississippi and the Volga—have been adopted. Circumstances, however, have to be favourable if they are to prove a satisfactory and economical arrangement. The Volga has its source in a lake and swamp region where land is cheap and unfit for agriculture. The dams required were only 17½ feet high, and a storage capacity of 35,000 million cubic feet was obtained. On the Upper Mississippi above St. Paul, five reservoirs were formed out of an extensive lake area of 480 square miles, with a storage capacity of 93,400 million cubic feet. It is stated that the increase in height obtained at St. Paul during the low water period—about 90 days—averages only 14 inches. The system is not regarded as sufficiently satisfactory to justify its extension elsewhere in the United States. Where there is no original headwater accumulation its adoption is out of the question.

RIVER DREDGING.

The improvement of river channels by means of mechanical dredging has received considerable impetus of late years by reason of the development in power and capacity of dredging plant. The various appliances are described in detail in connection with harbour dredging (*vide* p. 1542 *et seq.*). In some cases, as for instance the Volga, with its tributaries the Oka and the Kama, the application of dredging alone, without the assistance of artificial training works, has proved sufficient to ensure the maintenance of a serviceable channel, while in other cases, notably on the Mississippi and the Mersey, engineers employ both systems conjointly.

Dredging Plant on the Volga.—On the Volga, dredgers work from the shallowest depths up to 20 ft. and consist of both bucket dredgers and suction pumps.

One of the former has a hull 131 ft. by 26 ft. with a draught of 3 ft. 3 ins. It discharges about 300 cubic yards per hour by means of shoots, or 370 cubic yards per hour through a floating pipe-line. Two other dredgers have a length of 157 ft., a breadth of 31 ft. 2 ins., and a maximum draught of 4 ft. 11 ins. They are self-propelling with a speed of 4 knots. The pipe-line is 1,740 ft. in length. The buckets have a capacity of ½ cubic yard, and they are reinforced by centrifugal pumps of 5 ft. diameter. The pipe-line has a diameter of 19 ins. A still more recent dredger is 131 ft. long by 28 ft. wide, with a draught of only 2 ft. 4 ins , a dredging depth of 17 ft., and a working capacity of 196 cubic yards per hour in sandy material.

RIVER CANALISATION.

The canalisation of rivers is effected by dividing their beds into a series of reaches separated by dams, or weirs, which are provided with a communicating lock, or locks, arranged generally at one side. Dams are either fixed or movable, and they may also be permeable or impermeable. Fixed, impermeable structures are generally resorted to as being more economical in construction and more convenient in action. Movable dams may be said to be required only in cases of excessive flood flow, or where the conditions admit of free navigation during appreciable periods. Fixed weirs are usually constructed of solid stonework, rubble, piling or concrete provided with the requisite sluices and overflows. Movable weirs are more often of timber or iron framework with mechanism for lowering and raising them, either wholly or in part by means of leaves or panels. They are of various types with distinguishing names, such as Needle, Chanoine, Boulé and Bear-trap.

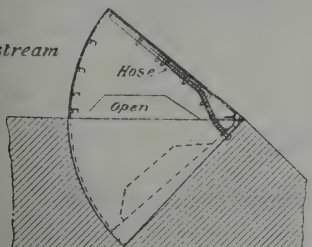

FIG. 1.—Section of Weir near Bremen.

Sector Weir near Bremen.—A notably large sector weir which constitutes a development of the bear-trap type, across the River Weser, near Bremen, is illustrated in cross sectional outline in fig. 1. The weir is in two lengths of 177 ft. each, and holds up the water on an average to a height of about 12 ft.; in winter, the height rises to 18 ft. The structure forms the hollow horizontal sector of a cylinder of 21½ ft. radius turning on a horizontal shaft, the angle of the sector being about 45 degrees. The weight of each sector is 129 tons. A description of the weir with the method of raising and lowering is contained in *Engineering* of July 7, 1916.

Lateral Canals.

As an alternative to river canalisation and where the channel exhibits features which do not conveniently lend themselves to treatment, an independent lateral canal may be constructed, generally following the lie of the river, but also making use of any facilities which may offer themselves for straightening and rectifying the course.

The River Rhone, in the chequered history of its amelioration, has been furnished with three lateral canals to overcome the difficulties of navigation at its natural mouth. Each in turn of the earlier two became inadequate for dealing with the traffic which accrued from its construction, and now there is a recently constructed artificial waterway to the port of Marseilles which is described in detail at p. 1578.

BRITISH CANALS.

The following summary of the conditions prevailing in Great Britain is extracted from the Report of the Royal Canal Commission (1909):

'On the whole, the waterways may be roughly divided into two classes, those having locks of more, and those having locks of less, than 14 ft. in width. Corresponding with these two classes of locks are two classes of vessels usually known respectively as barges and narrow boats, the latter being often called "monkey boats," and chiefly in use on the Southern and Midland canals of England. The barge usually measures from 60 to about 72 ft. in length by 14 ft. in width of beam; the narrow boat is about 70 to 72 ft. in length, but only 7 ft. in width. The narrow boat when loaded, and drawing about 3 ft. 3 ins. of water, will carry about 30 tons over many of the canals. The barge will carry about twice that weight, with the same draught. Both the narrow boat and the barge could carry a heavier cargo if the depth of water were increased sufficiently.

'The usual length of lock, both on the wider and the narrower waterways, in the South and the Midlands, is, accordingly, about 75 ft. But on the wider, or barge canals, the locks are usually between 14 and 15 ft. or more in width, and on the narrow canals between 7 ft. and 8 ft. In both classes of lock the depth of water on the sill varies, speaking very generally and with many exceptions, from 4 ft. to 5 ft.'

	Miles.	Chains
Canals with locks under 14 ft. (narrow)	1,165	5
„ „ „ over 14 ft. (barge canals)	762	29*
Navigations under 14 ft.	478	57
„ over 14 ft.	834	20

* Including the Manchester, Gloucester and Berkeley, and Exeter Ship Canals.

DEVELOPMENTS IN CANAL CAPACITY.

In France and South East Belgium the standard boat carries about 300 tons, while in Germany the newest canals are adapted to boats of 600 tons and upwards. In this country opinion as to future policy is divided between the adoption of the 300-ton type and the retention of the smaller class of boat in general use, not exceeding 100 tons. The following are the dimensions recommended for the two classes respectively by Sir J. Wolfe Barry and Partners, who were called in to advise the Royal Commission on the matter.

Dimensions.	100-ton Boat. Canal.	300-ton Boat. Canal.
Length of barge over all	80 ft.	115 ft.
Beam „ „	14 „	21½ „
Draught	5 „	6½ „
Area of immersed midship section of barge	69 sq. ft.	138 sq. ft.
Cross-sectional area of canal	350 „ „	690 „ „
Depth of canal	7 ft.	8½ ft.
Top width of waterway in open country	59½ „	92½ „
„ „ „ „ in towns	51½ „	83 „
Width of waterway at bridges	32 „	48 „
Minimum headway of new bridges	10 „	13 „
„ „ „ existing bridges	9 „	13 „
Ruling radius for bends of canal	12 chains	17 chains
Locks: Length, mitre to mitre of gates	253 ft.	266 ft.
„ Width between side walls	15 „	22½ „
„ Depth on sills	6½ „	8 „

600	196·7	23·3	5·9	51·3	7·9	3,018 / R	1,919	213·2	29·5	8·2
900	246·0	28·2	5·9	65·6	8·2	4,724 / R	2,690	262·4	34·4	8·2
1,200	295·2	32·8	5·9	77·7	8·4	6,888 / R	3,509	311·6	39·4	8·2

A boat, 24 to 25 ft. wide by about 200 ft. long, with 6½ ft. draught, has been recommended by experts as a suitable type for a 600-ton barge on the Canal du Nord.

On the Rhone, barges of the same width and 220 ft. long have been put into service, carrying 650 tons on a draught of 6 ft.

The type of boat on the Rhine is the lighter of 246 ft. by 36 ft., which with the same draught carries about 900 tons, but when immersed to 6½ ft. is capable of taking 1,200 tons, with a displacement coefficient of 0·75.

(*'Annales des Ponts et Chaussées,' March–April* 1920.)

Capacity of German Inland Waterways.

Inland waterways have reached a very high pitch of development in Germany. Certain inland harbours surpass important seaports in the amount of traffic handled The size of craft accommodated far exceeds anything attempted in this country. The following is a statement of the lengths of waterway available for successive grades of tonnage:—

	Tons.	Kilometres.
For vessels of	3,000 or more	615
,, ,, from	1,200–3,000	1,463
,, ,, ,,	600–1,200	2,064
,, ,, ,,	400– 600	2,607
,, ,, ,,	250– 400	1,705
,, ,, ,,	170– 250	1,565
Smaller vessels	—	4,515

An important project now in contemplation is the Rhine-Neckar-Danube Canal, which will complete the waterway connection right across Europe from the North Sea to the Black Sea. The length of the proposed canal will be about 165 miles, of which 125 miles come upon the Neckar section from Mannheim to Plochingen, and the remaining 40 miles on the section Plochingen-Ulm.

CONTINENTAL CANALS.

Canal du Nord, France, duplicating the St. Quentin Canal, which forms part of the navigable waterway connecting Paris with the Northern parts of France.—The ordinary cross-

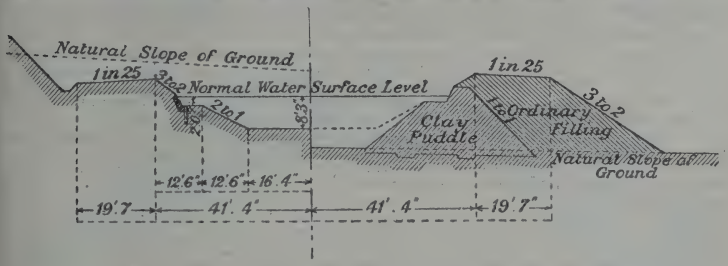

FIG. 7.—CANAL DU NORD.

Section in Excavation. Section in Filling on Impermeable Ground.

section has a minimum width of 33 ft. at the bottom and 39 ft. at a depth of 6½ ft., with a navigable depth of 8 ft. Towpaths, 13 ft. to 20 ft. wide on each bank, one for upstream and one for down-stream traffic. Locks provided to accommodate two 300-ton barges in tandem; dimensions, 279 ft. long by 19½ ft. wide by 8 ft. deep. Lifts, 13 ft. to 22 ft., with minimum reach of 1,100 yards between locks. Tunnels of two types: those for single train of boats are 33 ft. wide at springing of arch, and those for double trains of boats abreast are 52½ ft. wide at springing. Each type has two side platforms, 6½ ft. wide carried on piles. Largest tunnel at Ruyaulcourt, which is 2¾ miles long. Canal designed for mean speed of two miles per hour, with barges mechanically hauled. Fig. 7 gives typical sections.

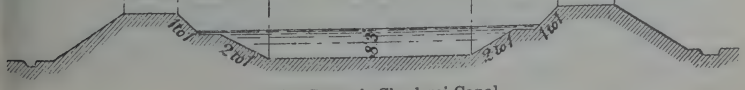

FIG. 8.—Brussels-Charleroi Canal.

The Rhone-Marseilles Canal.—Opened in 1926, the cross-section in the straight lengths gives a width of 82 ft. at a depth of 6½ ft., while the normal depth is 8 ft. 2 ins., and that in the outer portion approaching Marseilles 10 ft. Sills and inverts throughout are laid to this lower level, in order to admit of future deepening. The width of the canal is narrowed to 59 ft. where it passes through the Nerthe Mountain (Rove Tunnel). The canal section on the straight portion has been fixed at five times the immersed section of the present Rhone barges, when loaded to their maximum capacity of 600 tons on a 5 ft. 9 in. draught. These barges have a beam of 26 ft. 3 ins. The dimensions of the locks are 525 ft. internal length, by 52½ ft. in width. The lock at Arles has a lift of 23 ft. at low water. The total cost of the canal is stated to exceed 3,560,000*l.* The section of the Rove Tunnel shown in figs. 9 and 10 cost 52*l.* per ft. run of which the masonry work accounted for 16*l.* per ft. run.

Modern German Canals.—Herr Germelmann, in a Report to the Philadelphia Navigation Congress 1912, remarks that in Germany high economic value is attached only to large efficient canals, suitable for vessels of 213 ft. in length by 26¼ ft. in breadth (600 ton barges), or, at least, for vessels of 180½ ft. in length and 26¼ ft. in breadth (400-ton barges) with draughts of 5 ft. 9 ins. The cross-sectional area of canals recently constructed is as follows:—Spree-Oder Canal from 705 to 760 sq. ft.; Dortmund-Ems Canal, in cuttings, 640 sq. ft.; in embankment, 810 sq. ft.; Teltow Canal, 652 sq. ft.; Ems-Weser Hanover Canal, in cuttings, 662 sq. ft.; in embankment, 780 sq. ft.; Rhine-Ems Canal, 986 sq. ft.; Berlin-Stettin Canal, about 732 sq. ft.

Trollhätta Canal, Sweden.—This canal, first opened in 1607 and recently enlarged and extended at a cost of about 1,300,000*l.*, has a length of about fifty-two miles, and connects Lake Vänern with the Kattegat, between which there is, at ordinary water level, a vertical difference of 146 ft. The canal is built to accommodate vessels of 13 ft. 1½ in. draught, but with a view to future developments the locks are constructed to pass vessels of 16 ft. 5 ins. draught. The normal bottom width of the canal is 79 ft., but this, at passing places, is increased to 95 ft. and 115 ft. The maximum depth in rock cutting for vessels drawing 13 ft. 1½ in. is 14 ft. 5 ins., and in earth excavation, 18 ft. 3 ins. For the 16 ft. 5 in. vessel these dimensions are increased to 18 ft. and 19 ft. 7 ins. respectively. The lock chambers have a length of 295 ft. and a width of 45 ft., with 18 ft. of water over sills. The greatest change in level at any one lock is 26 ft.

New York State Barge Canal.—This canal, the inception of which dates back to the beginning of last century, has recently been enlarged so as to afford accommodation not only for the largest class of barges at present constructed, but also for those up to 3,000 tons which may be built in the future. A minimum depth of 12 ft. has been provided, with a minimum width of 94 ft. in rock cuttings and of 125 ft. in earth excavation. The locks, 57 in number, have chambers 310 ft. long and 45 ft. wide and are capable of passing vessels with maximum dimensions of 300 ft. by 42 ft. The lock at Little Falls has a range of 40½ ft., exceeding any single lift on the Panama Canal. The syphon lock at Oswego is the first of its type in the United States, and with a range of 25 ft. is probably the largest of its kind in existence. A description of it is as follows (*vide Engineering*, August 2, 1918). The general design of the culverts is not unlike that of an ordinary lock, except that at the upper and lower ends the culverts are curved upwards so as to form necks. These rise a little above the highest water level and are shut off from all communication with the outer air, except through the operating pipes. The flow of water in the syphon is started by means of tanks, one of which is built in each wall near the upper end, and communicates through pipes with the upper and lower levels and with both syphons in the same wall; they are shut off from all other communication with the outer air. The cycle of operations is as follows: The tank is first filled with water, then the intake valve is closed and the outlet valve opened. In consequence there is a body of water suspended by its weight, but tending to escape into the lower pool, and thus producing the necessary vacuum. Therefore, on opening the air valve, the air in the syphon rushes towards the vacuum, and water begins to flow up and over the crest in the neck. When using both syphons, the lock chamber can be filled in from 4½ to 5 mins., and it can be emptied in from 5½ to 6 mins. It has been found that the draught of the vacuum is such that, soon after the flow has started, the direction of the air is reversed and the vacuum is restored in the flask. The operating power is accordingly self-renewing except for a small amount of air leakage.

Cost of Canal Construction and Improvement in Great Britain.

In 1905 Mr. J. A. Saner estimated the constructional cost of new canal, suitable for two lighters of not less than 250 tons carrying capacity, or 200 tons when self-propelled, with locks 230 ft. by 22 ft. having 6½ ft. draught of water over sills, the canal itself being 40 to 45 ft. wide at bottom, 80 to 85 ft. wide at top, and 8 ft. deep in centre, at 30,000*l.* per mile, and the cost of improving existing routes to reach the same standard at 15,000*l.* 'These figures are based on the actual cost of the Weaver Navigation and the Manchester Ship Canal; the former has cost about 42,000*l.* per mile, and the latter about 440,000*l.* per mile, inclusive of docks in each case. The Worcester and Birmingham Canal originally cost 20,000*l.* per mile; and between 1879 and 1891 the French improved 2,500 miles of river, 2,250 miles of canal, and built 875 miles of new canal, for a total of 21,000,000*l.*, or an average of 3,734*l.* per mile; so that the foregoing figures should be ample.' (*Saner on Waterways in Great Britain, Min. Proc. Inst. C.E.*, vol. clxiii.)

RELATIVE ADVANTAGES OF LOCKS AND LIFTS ON CANALS.

Changes of level in canals and canalised rivers are effected by (1) locks, and (2) mechanical lifts, the latter being either (*a*) vertical or (*b*) on an inclined plane.

Locks are the simplest and most stable means of attaining the desired object. There is no question of their superiority for all differences of level up to 12 or 15 ft., and circumstances are generally favourable for their adoption for differences up to 25 or 30 ft., and even more. Among

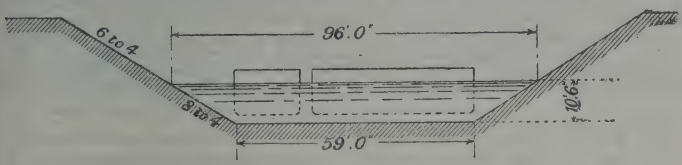

FIG. 15.—Bruges-Ghent Canal (General Section).

the older canals may be instanced a lock on the River Moldau, which has a lift of 29 ft., and another on the St. Denis Canal, which has a lift of 32½ ft. Such heights used to be considered as marking about the limit of the advantageous employment of locks over mechanical appliances. For

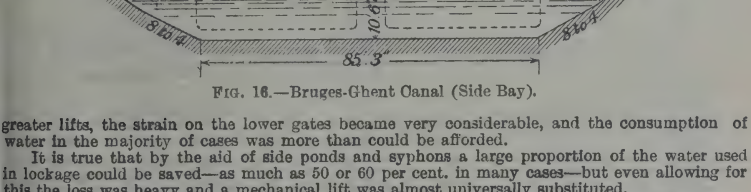

FIG. 16.—Bruges-Ghent Canal (Side Bay).

greater lifts, the strain on the lower gates became very considerable, and the consumption of water in the majority of cases was more than could be afforded.

It is true that by the aid of side ponds and syphons a large proportion of the water used in lockage could be saved—as much as 50 or 60 per cent. in many cases—but even allowing for this the loss was heavy and a mechanical lift was almost universally substituted.

In modern German practice, however, a very striking advance has been made owing to the development in size of vessels, which have now reached to a tonnage of 600 to 1,000 tons. A lock recently constructed at Henrichenburg has a lift of 46 ft. It is provided with five side ponds for the economisation of water, the saving amounting to about 76 per cent. The chamber (312 ft. long by 33 ft. wide with 9 ft. 10 ins. depth of water over sill) is built in concrete on a rock foundation, requiring an invert only 19¼ ins. thick. Other locks are being constructed which attain lifts of over 60 ft. The former limit therefore can no longer be said to apply, except in so far that, if it be exceeded, due provision will have to be made for the increase in strength of the gates and side walls, and for the economisation of water.

An appropriate test to apply to the serviceability of locks is the gradient or slope of the canal route. Where this is fairly regular and does not exceed 1 in 100 the rise lends itself to convenient subdivision into reaches of a quarter of a mile each, or more, separated by single locks of about 13 ft. lift. Under ordinary circumstances this is found to be a suitable standard for barge traffic, with barges of moderate tonnage, such as are customary in this country.

Where, on the other hand, the level of the ground changes abruptly, locks of higher lift or a series of locks may be employed, but only if an adequate supply of water is forthcoming to make good the loss from lockage. Where water is scarce it will be necessary to fall back upon some system of mechanical transfer.

Mechanical Lifts are generally more expeditious and time saving in action than locks, but they are also as a rule more expensive, and from their nature they are less durable and more liable to derangement.

From a number of examples of direct acting vertical lifts may be mentioned those at Anderton (Cheshire), Les Fontinettes (France), and Peterborough (Canada), *vide* figs. 17–19.

Lift at Anderton.—In this case the difference in level is 50 ft. The lift consists of two wrought-iron troughs, each 75 ft. long by 15½ ft. wide, originally worked hydraulically and counterbalancing one another, so that it was only necessary to reduce the depth of water in the lower trough by 6 ins. in order to set the apparatus in action. Owing to excessive wear and tear which developed in the hydraulic rams and cylinders, these were replaced in 1907–8 by a system of suspension gear passing over pulleys on an overhead gantry with counter weights at

the free ends of the ropes. The total weight so suspended is 1,000 tons, each of the caissons weighing 250 tons, of which 80 tons is iron and the remainder water. The reconstructed lift is worked electrically. The main 30 B.H.P. motor runs at about 750 revs. per min., and the large 6 ft. pulleys make about 1 revolution in 2 minutes.

Lift at Les Fontinettes, near St. Omer, France.—The lift consists of two iron troughs containing water and each capable of taking a boat of 300 tons. Each trough is bolted at its centre to the head of a ram or piston, working in an hydraulic press. The two presses are in intercommunication by means of a pipe and constitute an hydraulic balance, vertical movement being obtained by admitting a surcharge of water to the upper tank. The surcharge is 12 ins. in depth, equal to about 64½ tons weight. The difference in level is 43 ft. The troughs are 129 ft. 7 ins. long by 18 ft. 4½ ins. wide, with a minimum depth of water of about 7 ft. The ends are closed by lifting gates. The rams or pistons are 57 ft. long, 6 ft. 6¾ ins. diameter, and 2 ft. 8 ins. thick. They are formed in sections 9 ft. 2 ins. long, flanged inside, bolted together,

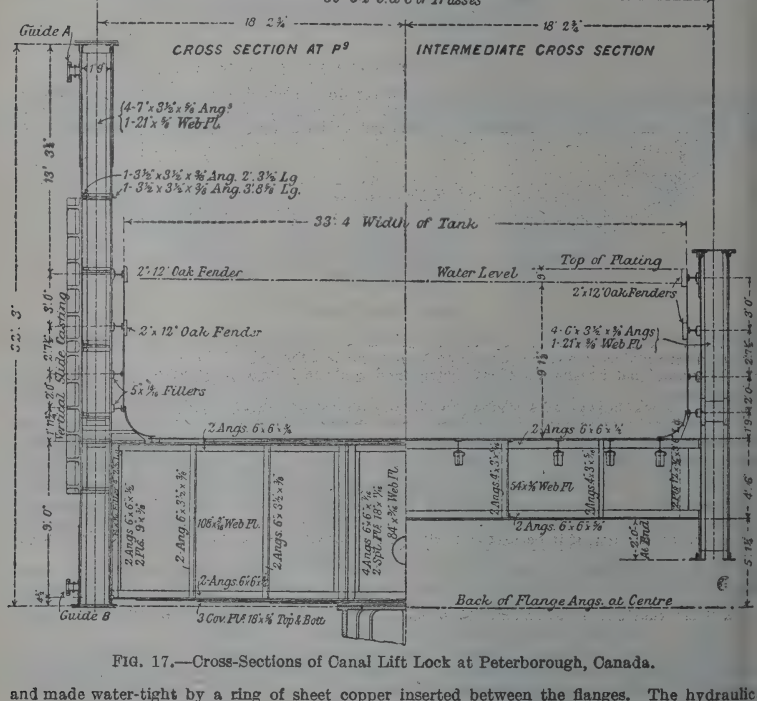

FIG. 17.—Cross-Sections of Canal Lift Lock at Peterborough, Canada.

and made water-tight by a ring of sheet copper inserted between the flanges. The hydraulic presses are 71 ft. high and 6 ft. 10 ins. diameter, resting upon concrete foundations at the bottom of excavated pits.

When one trough is raised to summit level there is a margin of 1¾ ins. between its upstream extremity and the downstream end of the canal aqueduct. At the moment of lifting the gates to allow of the passage of a boat in or out, the joint is made good by indiarubber hose running round the end of the aqueduct and protected by springs. This hose is inflated by air at a pressure of 1½ atmospheres. The same connection is made at the lower level.

The machinery consists of two turbines, one of 50 H.P. and the other of 15 H.P.

The actual time of descent and ascent of the troughs is five minutes. An entire operation, including entry and exit of barges, takes twenty minutes.

The total cost of the lift was about 74,800*l.*

Lifts on the Trent Canal, Canada.—There are two large lifts, one at Peterborough and the other at Kirkfield. The former consists of a pair of tanks, or chambers, 137 ft. long by

33 ft. 4 ins. wide, and with 9 ft. depth of water. Each tank is supported by a ram 7 ft. 6 ins. diameter worked hydraulically, so that the descent of one chamber automatically forces up the other. The range of lift is 65 ft. Under ordinary conditions the upper chamber is held in position at a level about 6 or 8 ins. below the limit of stroke, and this surcharge of water is sufficient, when the by-pass is open, to overcome friction and give the necessary movement. The tanks are supported by openwork lattice trusses, and the total load of water and steel is carried to the top of the ram by four plate girders 9 ft. deep. The following is a description of the gates, which are in pairs, one closing the chamber end and the other the canal reach. 'Each gate is made up of three main 15-in. channels, with a small plate and angle girder at the top, and is stiffened vertically by 10-in. I beams. In every space between these vertical I beams there are placed two galvanised iron air chambers about 11 ft. long. These have the effect of making the gates practically buoyant, and this decreases markedly the amount of work which has to be done in raising the gates from a horizontal to a vertical position. The water-tight plating is, in each case, on the outside of the gate, and the hinges are at the bottom. In the case of the lower reach gates and chamber gates, the hinge for the reach gate is 2 ft. 4 ins. below the hinge of the chamber gate, and 1 ft. 10 ins. separates them in a longitudinal direction. Consequently, the chamber gate is approximately 10 ft. deep, while the reach gate is about 12 ft. 6 ins. deep. As it is never necessary to operate any gate singly, the gates are arranged to work in pairs. At

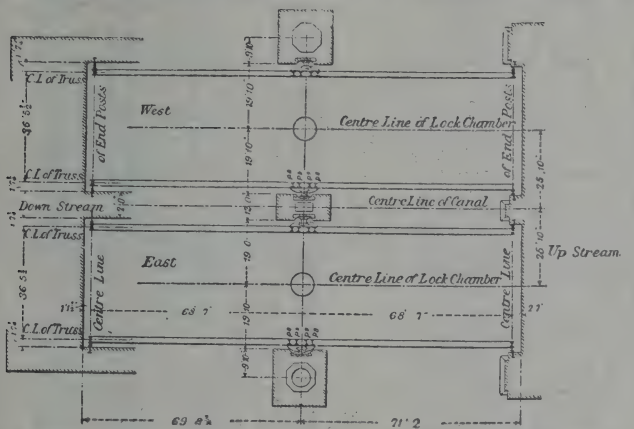

FIG. 18.—General Arrangement of Canal Lift Lock at Peterborough, Canada.

each end of the reach gate there is a pinion meshing into a circular rack set into the dock wall. The centre of the pitch circle of this rack is, of course, coincident with the centre of the hinge of the reach gate. The pinions above referred to are connected by a horizontal shaft running right across the gate, and power is applied to this shaft by means of a sprocket with chain, driven from another shaft, the centre of which is the same as that of the hinge. This shaft is actuated by one of the hydraulic gate engines provided.

'The seal between the reach-gate and the reach is accomplished by a small rubber strip, which lying over the adjacent surfaces is made water-tight by hydrostatic pressure. A similar arrangement is used for making the joints between chamber-gate and chamber water-tight. The seal between the end of the chamber and the end of the reach is accomplished by a collapsible rubber tube, which, when the chamber is away from the reach, lies almost flat against the end of the reach-gate frame. When, however, the chamber is in its proper position, the tube is inflated by compressed air at 90 lbs. per sq. in., and a water-tight joint is obtained.'

The hydraulic cylinders are plain steel castings, built up in flanged sections 5 ft. 3 ins. long. The inside diameter is 7 ft. 8½ ins., and the metal is 3½ ins. thick. The joint packing is of copper, ⅞ in. wide and $\frac{1}{16}$ in. thick, with $\frac{7}{16}$ in. diameter lead wire in press sections. The rams are of cast iron in flanged sections, also 5 ft. 3 ins. long, 30 ins. external diameter, thus giving a water space of 1½ in. completely round the rams. The jointing is the same as that for the cylinders, except that the lead ring is omitted.

A very full description of this lock appeared in *Engineering* of June 9 and 16, 1916, from which the above particulars were extracted.

Inclined Planes represent a class of mechanical appliances suitable for intermediate conditions, viz., a route gradient too steep for single locks with intermediate reaches, and not

(From Report by Col. H. F. Hodges, U.S. Army, to 12th Int. Nav. Cong., Philadelphia, 1912.)

sufficiently abrupt at any one point for a vertical lift. Generally speaking, gradients of between 1 in 8 and 1 in 10 are most favourable, but they may run up to 1 in 75, or 1 in 80, and, on the other hand, inclined planes are sometimes adopted where the rise is much steeper, as, for instance, at Foxton on the Grand Junction Canal, where the gradient is 1 in 4. The Foxton incline is similar in character to the balanced vertical lift, consisting of two caissons travelling transversely, each maintaining a barge of 70 tons afloat. It is claimed for inclined planes that, in comparison with locks, they save water, and, in comparison with vertical lifts, they save time, since a boat is travelling forward simultaneously with its alteration in level. Moreover, they do not require such deep or expensive foundations as the lift proper. In spite of these advantages, inclined planes have not attained a very marked degree of acceptance among canal engineers.

Canal Curves.—The formula adopted in Belgium for the increased width at curves is

$$S = \frac{A^2 + a^2}{R}.$$

Where S is the increase in bottom width to be added to the normal semi-width on the convex side of the curve, R is the radius of the curve, and A and a are the half lengths of the boats which have to pass one another. The units are all in metres, and the value of S must therefore be multiplied by 3·28 to bring it to feet. The increased width is splayed into the straight length at a distance of 2 (A+a) from the commencement of the curve.

LOSS OF WATER ON CANALS.

Rankine summarises the sources of loss of water on canals as follows:

Waste of Water by leakage of the channel, repairs and evaporation *per day* = area of surface of canal × ¼ of a foot, nearly.

Current from the higher towards the lower reaches, produced by leakage at the lock gates, *per day*, from 10,000 to 20,000 cubic ft. in ordinary cases.

Lockage.—Single locks are more favourable to economy of water than flights of locks. At a single lock, single boats ascending and descending, alternately, cause less expenditure of water than equal numbers of boats in trains. On the other hand, at a flight of locks, boats in trains cause less expenditure of water than equal numbers of boats ascending and descending alternately. For this reason where a long flight of locks is unavoidable, it is usual to make it double, using one flight exclusively for ascending boats and the other exclusively for descending boats.

Loss by Percolation from Erie Canal.
In Cubic Feet per Second per Mile of Canal.

Location.	Material in Bank.	Cub. ft. per Sec. per Mile of Canal.
Near Dunsbach Ferry	Gravel	1·68
Near East of Schenectady	Sandy loam	1·50
Near West of Schenectady	Gravel	2·24

West of Amsterdam	Coarse gravel	12·89
Canajoharie	Gravel	2·00
Fort Plain	Gravel	6·85
East of Utica	Sandy loam	4·45
East of Rome	Sand and gravel	8·48
West of Rome	Clay loam and gravel	1·75

Note.—The Erie Canal has bottom widths of 52½ ft. and 42 ft. and depths of 7 ft. and 9 ft. in various portions.

Canal Bank Protection in Italy.—The sandy banks along the Candiano Canal in the province of Ravenna are strengthened with a row of reinforced concrete piling. The king piles, 10 to 16 ft. long and 8 ins. square, are driven at intervals of 10 ft. They are secured together at the top by a longitudinal runner 8 ins. by 8 ins., behind which is driven a row of sheet piling from 5½ to 6½ ft. long and 2 ins. thick. The length of the piles depends upon the nature of the ground and the depth of water, and, where necessary, further security is obtained by anchorage tie rods and bars to short piles in the rear. At points where it was possible to remove the water from the canal, or where the bottom was occasionally exposed, it was considered desirable and economical to revet the banks with a surfacing of reinforced concrete 2½ ins. thick in which the reinforcement consisted of expanded metal ·4 to 1·6 in. mesh and ·2 to ·32 lbs. per sq. ft. Where the canal bottom is not subject to erosion during floods, this revetment is continued down as far as 18 ins. above the level of the bottom, and the toe is protected by rubble. In cases of erosive action there is a concrete foundation or sill, sometimes supported by piling; and where the water level cannot be lowered sufficiently for the formation of a sill, the toe of the revetment rests against sheet piling.

TRACTION AND HAULAGE.

Means of Traction.—On ordinary small barge canals horse traction has hitherto remained the principal means of traction, although locomotives have been tried from time to time, generally without success. On the larger canals, principally those on the Continent and abroad, tug haulage is frequently employed and some vessels are self-propelled. Ship canals are navigated by vessels under their own steam, but for passage through the locks of the Panama Canal electric locomotives are provided.

Horse Traction on a straight reach is most effective at speeds between 2½ and 3 miles per hour. Within these limits a steady pull of between 100 and 125 lbs. can be maintained, which is sufficient for loads up to 60 tons. There is the further consideration that at higher speeds the wash against the banks becomes excessive for unprotected surfaces. Where tugs or locomotives are employed some form of bank protection becomes essential.

As regards river navigation Rankine gives the following formula as a rough estimate of the effect of the current of a stream on the load which one horse is able to draw against at a walk.

Load drawn against current = load drawn in still water $\times \left(\frac{3{\cdot}6}{3{\cdot}6 + v}\right)^2$: v being the velocity of the current in feet per second.

Cable Towage.—Lévy system, as adopted on St. Maur Canal between Paris and Joinville.—Cable weighs 2·45 lbs. per lin. ft. Set with permanent tension of five tons. Breaking strength 50 tons. Deflection due to haulage does not exceed 4 ins. Vertical supporting pulleys are 2 ft. 7½ ins. diameter, and have depth of groove of 7¾ ins. Circuit may cover distance of 10 to 11 miles, so that two driving machines may be set 20 to 22 miles apart. For a speed of 1½ miles per hour 2 H.P. is required to draw a barge loaded with 350 tons. For a speed of 2¼ miles an hour 4½ H.P. is required. Tractive force = $\frac{Wv'}{2gl}$, where W = weight of boat in lbs., v = velocity in ft. per sec., g = acceleration due to gravity = 32 ft. per sec. per sec., and l = length of towline in feet. For a boat of 300 tons a velocity of 3 ft. per sec. and length of line of 300 ft., the tractive force = 315 lbs. Estimated cost of plant, about 12*s.* 6*d.* per lin. yd. Cost of working ranges from ½*d.* to ¼*d.* per ton per mile.

(*Report of Dr. Watson to Water Commerce Congress at Chicago*, 1893.)

Electric Traction on an elaborate scale has been installed on the Teltow Canal in Germany since 1905. The tractors run on rails on both banks. The current is continuous at 550 volts, from overhead mains, and each locomotive is driven by two 8 h.p. motors, which are sufficiently powerful to haul two 600-ton barges at a speed of 2½ miles per hour. A similar system is in use on the Douai section of the Canal d'Aire, where the tractors are of 10 h.p. In 1918, some petrol locomotives of 20–25 h.p. were introduced on the Rhine-Rhone Canal in place of horses, but though the experiment was successful the system did not come into general use on the Canal because it would have entailed considerable alteration in the permanent works.

The following advantages among others have been claimed for the use of electric tractors in place of steam tugs:—

1. Assuming that the electric lines are laid on each bank, there will be greater regularity and uniformity of speed in the service than where tugs are used, and there will be less delay in despatching cargoes at short notice and at regular intervals.

2. The banks and bottom of a canal are not so much injured by electric-towing as by tug-towing. In the latter case the peculiar disturbance to the bottom, with consequential injury to the side banks, caused by the motion of the screw, is added to the wave from the moving boats common to each mode of transport.

3. In the case of electric towing there is considerable economy of space and water in locks and lifts, because tugs and steam boats, which, by reason of their machinery, have a smaller cargo-carrying capacity than barges of like dimensions, need not be taken through.

4. Electric power, when once installed along a line of waterway, can be utilised not only for traction, but also for operating locks and other works, and lighting the waterway at night, and can even, perhaps, be utilised for factories establishing themselves along the waterway.

(*Report of Royal Commission on Waterways*, 1909.)

In 1924 there was installed, on a short section of the canal from the Marne to the Rhine, a new system of electric traction known as the Chenean system. The underlying principle is the utilisation of an electric tractor, with proportional contact, travelling on an aerial cable. Owing to the light weight of the tractor (about 12 cwts.) it is possible to space the supports of the aerial cable, in general, at about 20 yards distance. The cable is of steel, 9 in. diameter, weighing ¾ lbs. per lineal ft. The speed of movement varies from 1 mile per hour in narrow cuttings, tunnels, etc., to 2 miles per hour and over in the open.

SHIP CANALS.

General Considerations.—It is desirable that the ratio of cross sectional area of the cana to the immersed section of ships, where the traffic is commercial, should not be less than 4 to 1 and it may with advantage be much higher. In the Suez Canal it is about 7 to 1. For vessel of war, the ratio may be slightly less, as, for instance, in the Kiel Canal, where the ratio is about 3½ to 1. The limiting value is, however, dependent on the speed at which vessels are permitted to travel. In the artificial portion of the Suez Canal the speed is limited to between 6 and 7 knots, and about 8 knots represents an approximate upper limit for narrow shallow waterways. In passing through such waters vessels sink to a lower level than in the open sea on account of the displacement. Thus pilots have a rough rule that when a ship is near the bottom her 'squat' or 'sinkage' in feet may be about one-fifth of her speed in statute miles per hour.

For curves, M. Quellenec, Consulting Engineer to the Suez Canal Commission, recommends widening the bottom so that the longest vessel may preserve in its own direction a free space equal to 1½ times its own length from the slope of the concave side. The formula used on the canal was:

$$W = \sqrt{R^2 + (2a)^2} - (R + b);$$

where,

W = amount of widening in feet;
R = radius of axis in feet;
a = length of ship in feet;
b = ½ bottom width (on tangent) of canal in feet.

Kiel, or North Sea and Baltic Canal.—This canal, which connects the North Sea and the Baltic, was originally constructed between 1887 and 1895 at a cost of about 7,800,000*l.*, including land purchase. It has a length of 61½ miles. The former dimensions have since been very considerably increased, viz., the bottom width from 72 ft. to 144½ ft., the surface width from 226 ft. to 334½ ft., the depth from about 30 ft. to 36 ft., and the cross-sectional area from about 4,500 sq. ft. to 8,868 sq. ft.

At the entrances at each end of the canal there are now twin locks of 1,083 ft. available length, by 147½ ft. clear width and 45 ft. 2 ins. sill depth at mean water level. These locks take the place of the earlier locks, which were 492 ft. long by 82 ft. wide with 32 ft. of water over sill. The new locks are constructed in concrete, and each has three pairs of caissons dividing the chambers into lengths of 725 ft. and 330 ft. The improvement works cost 11,000,000*l.*, and were completed in 1914, one month before the war.

Manchester Ship Canal.—The Manchester Ship Canal was constructed between 1887 and 1893. It has a total length of 36 miles and includes four sets of locks, with an average

MANCHESTER SHIP CANAL: TYPE SECTIONS.

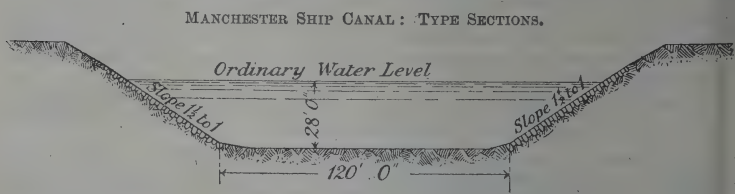

FIG. 20.—Ordinary Section.

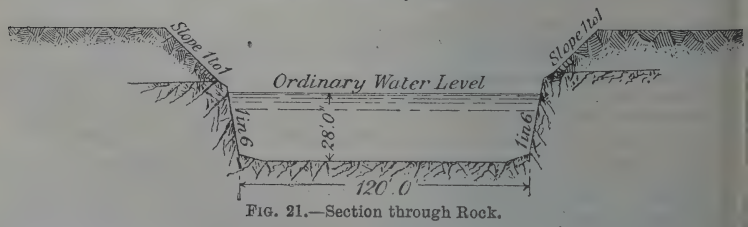

FIG. 21.—Section through Rock.

lift of 15 ft. each, about 160 acres of docks with warehouses and railway sidings, six high level bridges, seven swing bridges, and a swing aqueduct. The cost was 13,500,000*l.*, including land

purchase and promotion, the actual constructional cost being about 9,000,000*l.* The bottom width is 120 ft. The original depth was 26 ft., but this has now been increased to 28 ft. The average annual cost of maintenance is stated to be about 2,000*l.* per mile of canal.

Suez Canal.—The length of the Suez Canal is about 100 miles. It was opened in 1869, the cost of construction, apart from promotion, etc., having amounted to 10,680,000*l.* It has been progressively deepened so that the authorised maximum draught for ships in the canal has been as follows:—

From	1870 to 1890	7 m. 50	= 24 ft. 7 ins.
„	1890 to 1902	7 m. 80	= 25 ft. 7 ins.
„	1902 to 1906	8 m. 00	= 26 ft. 3 ins.
„	1906 to 1908	8 m. 23	= 27 ft. 0 ins.
„	1908 to 1914	8 m. 53	= 28 ft. 0 ins.
„	1914 to 1915	8 m. 84	= 29 ft. 0 ins.
„	1915 to 1920	9 m. 15	= 30 ft. 0 ins.
„	1921 to 1924	9 m. 45	= 31 ft. 0 ins.
„	1925	9 m. 75	= 32 ft. 0 ins.

The canal is in process of being deepened throughout to 12 metres, or 39 ft. 4 ins. A depth of 34 ft. has been attained.

Of the total length of 99·86 miles, 90·08 miles are in straight reaches; 3·48 miles in curves of 3,280 to 3,500 yds. radius; 4·97 miles in curves of 2,187 to 3,270 yds. radius; 1·11 miles in curves of 1,105 to 1,930 yds. radius; and ·22 mile with a curve of 321 yds. radius. These curves are in process of being modified so that the minimum radius shall be over 2,200 yds.

SUEZ CANAL.

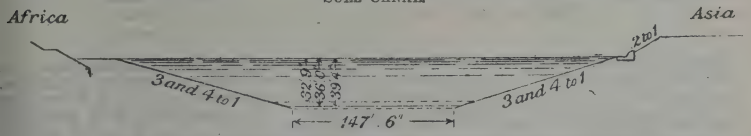

FIG. 22.—Section of Suez Canal, showing progressive deepening, as completed, in course of execution, and contemplated.

There are no locks, the canal being level throughout. At the Suez entrance there is a tidal range, amounting to about 6 ft. in the average at springs. The current flow does not exceed about 3½ ft. per second.

Panama Canal.—The total length of the Panama Canal, measured along its axis, is 50½ miles, but the portion actually within land area between coast lines is only 41½ miles. Of the total length, 14½ miles are at sea level, over 23½ miles in Gatun Lake, nearly 3 miles in locks or alongside approach walls, 1½ miles in Miraflores Lake, and 8 miles in the Gaillard Cut. The

DIAGRAMMATIC SECTIONS OF PANAMA CANAL. (Not to Scale.)

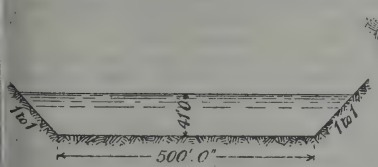

FIG. 23.—From Mindi River to Gatun Locks, and from Miraflores to Panama Bay.

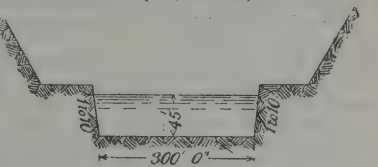

FIG. 24.—Gaillard (formerly Culebra) Cut.

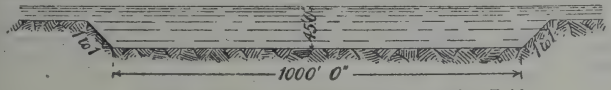

FIG. 25.—From Gatun Locks to Angle North of San Pablo.

summit level is 85 ft. above sea level. The depth lies between 40 and 45 ft. The bottom width varies as follows: For 16 miles the canal is 1,000 ft. wide; for 4 miles, 800 ft.; for 22 miles, 500 ft.; and for 8 miles, 300 ft. wide.

There are six pairs of locks with dimensions of 1,000 ft. in serviceable length and 110 ft. in width; three of these are at Gatun, one at Pedro Miguel, and two at Miraflores. The sills are laid so as to afford a depth of 40 ft. in salt water, and 41 ft. 4 ins. in fresh water. With the exception of the lower lock in the Miraflores flight, the chambers are provided with intermediate gates, dividing them into two sections of 600 ft. and 400 ft. The range of lift of the Pedro Miguel Lock is 30½ ft. All the locks are double, i.e. with parallel chambers, so that vessels may pass in opposite directions. At the Gatun flight the lift is 85 ft. divided among the three locks; the actual operating pressure between consecutive locks is therefore nearly 60 ft.

There are 46 pairs of lock gates, constructed of mild carbon steel with yokes and pintles of vanadium steel. The height of the gates varies from 46 ft. to 82 ft. The largest gate weighs about 700 tons.

The approximate cost of the canal, including purchase money, is 75,000,000*l.*

The following is a statement of the unit cost of excavating the Culebra (now Gaillard) Cut for the year 1912:

	Cost per cub. yd.
Transportation	$0·1331
Drilling and blasting	·1157
Tracks	·0885
Loading by steam shovels	·0681
General expenses and supervision	·0503
Dumps	·0479
Plant, arbitrary	·0395
Drainage, structures and clearing	·0045
Total unit cost	$0·5476

Bruges Ship Canal.—The canal connecting Bruges (Belgium) with the sea was constructed between 1896 and 1907. The works comprised an outer harbour with breakwater at Zeebrugge, and a sea-lock with a chamber 518 ft. long, 65½ ft wide, the sill being laid at 19 ft. 8 ins. below L.W.O.S.T., giving a depth of 31 ft. 8 ins. at H.W.O.N.T. The canal proper is 6¼ miles long, 72 ft. wide at the bottom, and 229 ft. wide at water surface level. There is a depth of 26 ft. throughout, and the side slopes are about 3 to 1. Two railway and three road bridges cross the canal. At Bruges there are two basins and a lock connecting with the internal barge canal system of Belgium.

Amsterdam, or North Sea Canal.—The distance from Amsterdam to the North Sea on the line of the canal is 15½ miles, and the route traverses two large shallow lakes. As originally constructed, the canal had a depth of 23 ft. and a bottom width of 88 ft. 7 ins. The entrance locks were three in number, the largest having an available length of 738 ft., a width of 82 ft., and a depth on sill of 33 ft. 6 ins. at ordinary low water. A new lock is now in course of construction, with a length of 1,313 ft., a breadth of 164 ft., and a depth of 49 ft. The canal itself is designed to be deepened to 49 ft., and to have a bottom width of 328 ft.

New Welland Canal, Canada.—The New Welland Canal was begun in 1913. Work was interrupted from 1917 to 1919 on account of the war. Completion may be expected about 1929. It is estimated that over $115,000,000 will be spent to complete the work.

The present Welland Canal locks overcome the 325·5 ft. difference in elevation between Lake Ontario (elevation 247) and Lake Erie (elevation 572·5) in 26 lifts. The locks have a usable length of 270 ft. and clear width of 45 ft. and depth over sills of 12–14 ft. The present canal cost $31,031,226 for construction, and $9,237,961 for maintenance to 1920.

The new canal project provides for seven locks to overcome the total lift of 325·5 ft., or 46·5 ft. lift per lock. Two additional guard locks are provided, one at each end of the canal, to provide for high and low water differences in the level of the lakes. These locks have a usable length of 800 ft., clear width of 80 ft., and depth over sills of 30 ft.

The new Welland Canal is to be excavated to 25 ft. in depth now, and later to 30 ft. When completed it will provide clearances, so that any ship passing through the lock at Sault Ste. Marie can continue to Lake Ontario. Later the Canadian Government expects to provide a waterway of equal dimensions from Lake Ontario down the St. Lawrence River. There is a difference of elevation between Lake Ontario and the river at Montreal of 221 ft.—(*Extract from Report by Edward H. Schulz to the 13th International Congress of Navigation, London*, 1923, *modified by later information.*)

STEAM.

When water is converted into steam by the addition of heat no steam is produced until the temperature of evaporation, or boiling point, is reached. This temperature increases with, and is determined by, the pressure. Whilst evaporation is taking place the temperature remains unchanged, and for this reason the heat required during this process is called the 'latent' heat. After the water has all been converted into steam, the addition of further heat raises the temperature and is said to superheat the steam. These general remarks apply to the vapours of all liquids, but the temperatures of evaporation at equal pressures vary widely with different liquids.

If steam contains liquid moisture mixed with it, it is said to be wet. The percentage of actual steam to total steam and moisture is the dryness fraction.

When the steam is not superheated, but yet contains no moisture, it is dry and saturated. The degree of superheat is measured by the rise of temperature above that of saturated steam.

The heat required to superheat steam varies with the pressure and temperature (see Table IV., p. 1597), but is roughly 0·55 B.Th.U. per pound of steam for each degree Fah. of superheat.

Superheating does not alter the pressure of the steam, but increases its volume in proportion (roughly) to the amount of superheat.

The volume of superheated steam may be determined approximately from the equation

$$V = v(1 + \cdot 0015 t_s)$$

where,

v = volume of dry saturated steam at the same pressure; t_s = degrees of superheat Fah.

For the mean specific heat, heat required to superheat, and total heat of superheated steam, see Tables III., IV., V., pp. 1596, 1597.

One cubic foot of water at 70° F. weighs 62·3 lb. At 212° the volume of this weight of water will be 1·04 cub. ft., an increase of 4 per cent. If the water is turned into saturated steam at 100 lb. gauge pressure, its volume will be 242 cub. ft. At 212° the volume of this weight of saturated steam will be 1,670 cub. ft., and at an absolute pressure of 1 in. of mercury it will be 11,000 cub. ft.

Steam Tables.

Prof. Callendar has established equations correlating the principal properties of steam, dry and saturated, superheated and supersaturated. His tables, based on these equations, agree well with the most reliable experimental observations and are also thermodynamically consistent.

In the following Table I., the total heat, volume, and total entropy of steam are abstracted from Callendar's Tables, published by Edward Arnold, London. The remaining data in Table I. and the other following tables have been calculated on the basis of Callendar's figures.

* British Engineering Standards Association 'Glossary of Terms used in Electrical Engineering.' The value 3,415 is based on the British Thermal Unit, which is defined as the quantity of heat required to raise the temperature of 1 lb. of water from 60° F. to 61° F., and is equal to 1·054 joules. See also p. 2192.

It has been established that under certain conditions of expansion, as in turbine nozzles steam may for a time not be in stable thermal condition, continuing to behave like a vapour although for equilibrium at the prevailing pressure and temperature a portion of it must become condensed. In other words, condensation is temporarily delayed. Steam in this condition is said to be 'supersaturated,' or, since its temperature is lower than the saturation temperature corresponding to the pressure, to be 'supercooled.' This condition is important in connection with the study of steam turbines.

Atmospheric pressure in this country is taken as 14·69 lbs. per square inch. At this pressure water boils at 212° Fahr., and has a latent heat of 970 British Thermal Units (B.Th.U.) per pound.

Steam at a pressure of 459 lbs. per sq. in. absolute, has a temperature of 459° F.

Gauge pressures are measured above atmospheric and are approximately 15 lbs. per square inch below the absolute pressures.

One inch of mercury column at 32° Fahr. is equal to 0·491 lb. per sq. in. Reduce one hundredth per cent. for each extra degree Fahr. of mercury column temperature.

Table IV. gives the extra heat, above the total heat of saturated steam given in Table I. contained in superheated steam from water at 32° Fahr. The heat added to the water and steam from any higher temperature is less than the value in the table by the number of degrees above 32 from which the heating of the water commences (approximate).

TABLE IV.—HEAT REQUIRED TO SUPERHEAT ONE POUND OF STEAM.

Pressure, Lbs. per Sq. In. Absolute.	Superheat, degrees Fahrenheit.						
	50	100	150	200	250	300	350
20	25·17	50·02	74·62	99·02	123·3	147·5	172·0
30	25·59	50·73	75·54	100·2	124·7	148·9	173·2
40	25·94	51·35	76·43	101·2	125·7	150·2	174·6
50	26·26	51·93	77·20	102·1	126·9	151·4	175·8
60	26·62	52·47	77·92	103·0	127·9	152·5	177·0
70	26·82	52·90	78·55	103·8	128·8	153·5	178·1
80	27·10	53·39	79·20	104·5	129·7	154·5	179·1
90	27·35	53·82	79·76	105·3	130·5	155·4	180·1
100	27·44	54·25	80·33	106·0	131·3	156·2	181·0
120	28·00	55·06	81·43	107·3	132·8	157·9	182·8
140	28·41	55·78	82·42	108·4	134·2	159·4	184·5
160	28·75	56·52	83·31	109·5	135·4	160·8	186·0
180	29·09	57·05	84·17	110·6	136·6	162·1	187·5
200	29·36	57·66	85·0	111·6	137·8	163·5	189·0
250	30·2	59·07	86·9	114·0	140·5	166·4	192·5
300	30·9	60·3	88·6	116·1	142·9	169·0	195·0

Example.—The total heat of steam at 160 lbs. absolute, superheated 150 degrees, from water at 102° F., is approximately as follows. (There is a slight inaccuracy owing to the specific heat of water varying a little, which can be discovered and checked from the third column of Table I.)

Total heat of saturated steam from 32°	=	1201 B.Th.U.
Deduct 102° − 32°	=	70 ,,
Net heat of saturated steam from 102°	=	1131
Add heat of 150° of superheat	=	83
Total heat as required	=	1214 ,,

TABLE V.—TOTAL HEAT OF SUPERHEATED STEAM.

Steam at Very High Pressures.

Increasing attention is now being directed to the use of steam generated at very high pressure and temperatures, and researches are being carried out to gain more accurate information i reference to the same.

TABLE VI.—PROPERTIES OF STEAM AT HIGH PRESSURES.

(Abstracted from Callendar's ' Enlarged Steam Tables.')

P = absolute pressure lbs. per sq. inch ; H = total heat, B.Th.U. per lb. ; V = volume of 1 lb steam in cub. feet ; ϕ = entropy ; t_s = saturation temperature ° F.

Temperature. ° F.	P = 400. t_s = 445·5.			P = 500. t_s = 468·6.			P = 600. t_s = 488·3.

At about 3,160 lbs. per sq. in. absolute, steam is in the 'critical' state, there being then no urface of separation between liquid and vapour; the latent heat is zero, the total heat (at aturation) is about 890, and the volume about 0·052 cub. ft. per lb. The generation of steam at he critical pressure (followed by throttling to a lower pressure for use in a turbine) is the charac- eristic feature of the recently invented 'Benson' boiler.

Equivalent Evaporation.

The factor of equivalent evaporation 'from and at 212°' is found by dividing the actual otal heat of steam as calculated or found from foregoing tables, by 970, which is the latent eat of steam, or heat of evaporation, at atmospheric pressure.

Example.—If the actual total heat is 1067, the factor is 1·1. This means that if the actual vaporation of a boiler is 8·0 lbs. of water per lb. of coal, the 'equivalent evaporation from nd at 212°' is 8·0 × 1·1 = 8·8 lbs. This basis is widely used because it renders the performance boilers accurately comparable on a uniform basis.

To Calculate the Amount of Steam required to Heat a given Quantity of Water.

G = gallons of water; T and t = temperatures, Fah., after and before heating; 10 × G × $(T - t)$ = B.Th.U. added to the water; H = total heat per lb. of steam (column 5, Table I., 1594); H − T + 32 = heat given to water by each lb. of steam; W = lbs. of steam required; en,

$$W = \frac{10 \times G \times (T - t)}{H - T + 32}$$

Note.—One cubic foot of water contains 6·24 gallons. The volume of each lb. of steam is ven in Table I.

Flow of Steam from an Orifice or Nozzle.

A jet of steam issuing from a vessel under pressure first contracts in section, and then expands the drop in pressure is more than about 42 per cent. of the absolute pressure in the vessel. The solute pressure at the narrowest section, which corresponds to the neck of a turbine nozzle, ries a little, but averages about 58 per cent. of the initial pressure for saturated steam, and out 55 or 56 per cent. for superheated steam. The velocity of the steam at this narrowest ction is nearly constant except at very low pressures.

For typical values of velocity and discharges, see Part IV., Steam Turbines, p. 1819.

When the drop in pressure is less than 42 per cent. of the absolute initial pressure, the full locity and contraction of section do not occur, and the above data do not hold (see Part IV., eam Turbines, p. 1819).

Or the quantity discharged per minute may be approximately found by Napier's formula

$$W = 6\,a\,p + 7,$$

where,

W = weight in pounds; a = area in square inches; p = absolute pressure.

The theoretical flow requires to be multiplied by $k = 0{\cdot}93$ for a short pipe, or 0·63 for a thin opening, as in a plate or a safety valve.

Where the steam flows into a pressure more than two-thirds the pressure in the boiler, then

$$W = 1{\cdot}74\,a\,k\,\sqrt{p_2\,(p_1 - p_2)}, \text{ approximately,}$$

where a, k are as above, and p_1, p_2 are initial and final pressures.

Power Plant Thermal Efficiencies.

In the diagram (p. 1601) the steam pressure is in *absolute* pounds per square inch, and the object is to divide up the over-all thermal efficiency of a power plant between the boiler plant (which includes superheater and economiser) and the turbo-generator plant.

Take, for instance, the 80 per cent. boiler efficiency line, which is about as high as can be expected in year-in and year-out working. From this it will be seen that 1,595 B.Th.U. must be applied to the boiler furnace to obtain 1 lb. of steam at a total heat of 650° F.

The best thermal efficiency practicable year in and year out, and even then only obtainable on a very high load factor, is a turbo-generator consumption of 11 lbs. per k.w.hr. (See Curve B.) This, combined with the boiler efficiency, gives a thermal efficiency over all of 19·4 per cent., or 17,550 B.Th.U., applied at the boiler furnace per kw.hr. It is questionable whether better results than this can be obtained until higher total temperatures than 650° F. can be worked to.

It is quite easy to arrive at a boiler efficiency and the efficiency of a turbo-generator separately, but these data do not give the power station engineer the year-in and year-out over-all thermal efficiency of a power plant from the fuel to the switchboard. This over-all figure, which has now reached 17 per cent. in some large power stations in this country, working on a load factor of about 60 per cent., is likely to be increased in the near future; it must take into account *all losses*, that is to say, the power required for operating a power station itself. These losses include lighting, motors, pumps (whether steam or electrically driven), condensing plants, cooling tower equipments, etc., also leakages due to blow-down of boilers, traps, drains and so on. The station may have a high boiler efficiency, and a high turbo-generator efficiency while the over-all efficiency may be very low, and very often is, because the consumption of power for driving the power station is frequently overloaded.

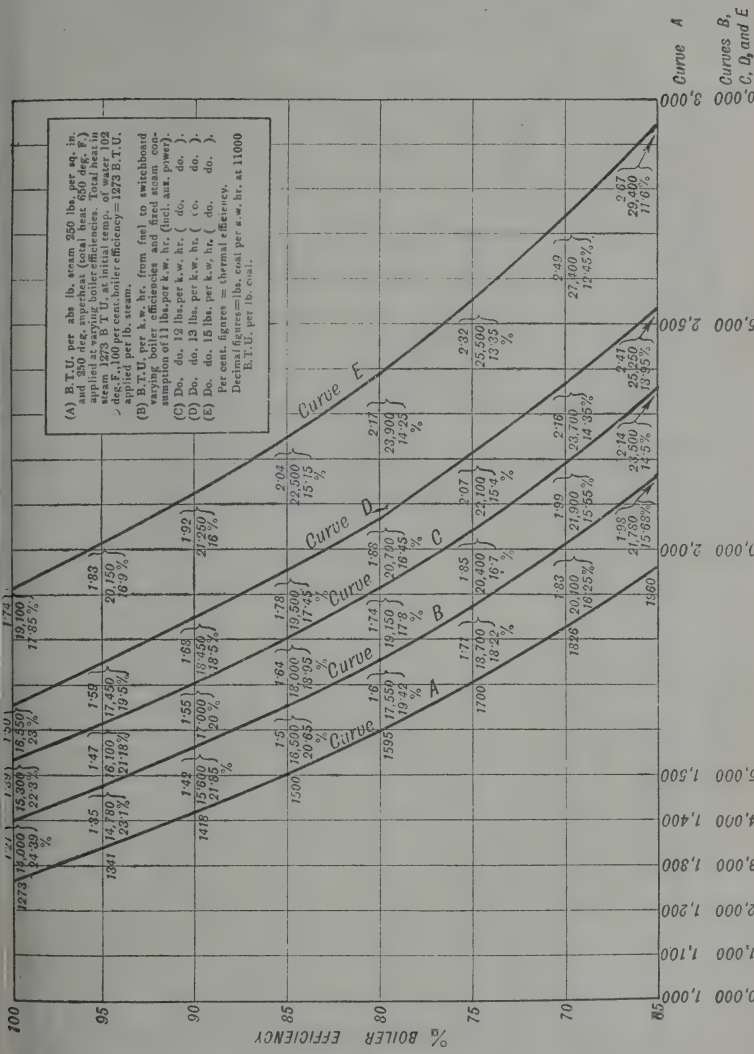
(*A. Hugh Seabrook, A.M.Inst.C.E.*)

At a discussion on Power Station Design at I.M.E.A. Convention, June 1920, the view was expressed by Selvey that 17,500 B.Th.U. per unit generated was then in sight, or 19·5 per cent over-all efficiency; and Mr. Ferranti was of the opinion that 28 per cent. would be attained with steam plant, eventually.

It is claimed that during October and November 1926 the station thermal efficiency at Columbia Power Station, U.S.A., attained 27 per cent. In this station pulverised coal is used, there are economisers and air pre-heaters, boiler pressure is 600 lbs. per sq. inch, and the steam is superheated to 730° F. The power units are two 45,000 kw. turbines, with four Babcock and Wilcox boilers for each. Steam is bled from the turbines at three stages for feed heating. Steam leaving the H.P. turbines at 80 lbs. per sq. in. is reheated to 700° F. before it passes to the L.P. turbines.

The boiler plant efficiency is over 89 per cent, and the load factor is exceptionally high, from 60 to over 80 per cent.

(*The Engineer*, Sept. 23, 1927.)



(A) B.T.U. per abs lb. steam 250 lbs. per sq. in. and 250 deg. superheat (total heat 650 deg. F.) applied at varying boiler efficiencies. Total heat in steam 1273 B.T.U. at initial temp. of water 102 deg. F., 100 per cent. boiler efficiency = 1273 B.T.U. applied per lb. steam.

FUEL CONSUMPTION AND THERMAL EFFICIENCY OF STEAM ELECTRIC POWER STATIONS.*

The reports on the output and fuel consumption of steam electric power stations in Great Britain, published by the Electricity Commissioners, classify the stations into thirteen groups according to output. For four of these groups, representing the largest, the smallest, and two intermediate sizes of station, the following figures are abstracted from the report for the year ending March 31, 1926 :—

Output of Station Units in Year.	Over 200,000,000.	Between 10,000,000 and 25,000,000.	Between 500,000 and 1,000,000.	Under 50,000.
Number of stations in group . .	5	63	26	10
Total units generated by steam plant .	1,241,324,725	1,036,661,966	19,260,935	302,143
Total fuel consumed . . . tons	1,048,135	1,289,205	63,901	1,797
Average fuel consumption per unit generated . . . . lbs.	1·89	2·77	7·37	12·96

	1926 Report.	1925.
Total output of all steam stations . units	7,804,482,933	7,090,756,650

STEAM GENERATING PLANT.

BOILER DESIGN—TRANSMISSION OF HEAT IN BOILERS — BOILER EFFICIENCY — BOILER SHELLS — STANDARD CONDITIONS FOR THE DESIGN AND CONSTRUCTION OF MARINE BOILERS — BOILER TUBES — TYPES OF BOILERS — BOILER SETTING — CHIMNEYS AND FLUES—SUPERHEATERS — SCALE AND CORROSION — FEED-WATER SOFTENING — FEED HEATERS — ECONOMISERS — AIR HEATERS — INSPECTION AND LEGISLATION — BOILER FITTINGS — DAMPERS — INJECTORS — SAFETY VALVES — GAUGES—REGULATORS — CLEANERS — STEAM PIPES—STEAM TRAPS.

BOILER DESIGN.

General Considerations.

Simplicity and accessibility for cleaning, favour the tank type of boiler, of which the Lancashire is the best known. The ratios of heating surface to weight and space occupied are, however, necessarily low, and for large units or intensive generation of steam, the tubular boiler has advantages. In order that these advantages may be fully developed, certain problems must be recognised and dealt with, namely—

(*a*) Boiler deposits must be reduced to a minimum, and these constrained in suitable mud drums and other parts.

(*b*) Water and steam spaces must be accessible for cleaning and inspection with a minimum of time and labour for joint breaking and making.

(*c*) Combustion of coal (or oil or gas) in large bulk must be arranged for.

(*d*) As much as possible of the heating surface should be exposed to direct radiation from the furnace and combustion chamber. The remaining heating surface should be large in relation to length of path of gases.

(*e*) The boiler must be capable of dealing with overloads.

The first two, (*a*) and (*b*), used to receive more attention than the other points, but (*c*) and (*d*) are now recognised to be of very great importance.

The efficient combustion of fuel requires that the particles of combustible, whether solid, liquid, or gaseous (including the products of the volatilisation of coal or oil), should be brought into intimate contact with air in the furnace.

In general this requires a large combustion chamber and a long path for the flame before it reaches the tubes or plates of the boiler, so that ample space and time for combustion are ensured.

Large water-tube boilers were at one time unduly limited in combustion space, and in recent years combustion chambers and flame paths have been much increased. A tendency is now showing itself to avoid further increase, and even to reduce combustion space as compared with recent designs, and to secure efficient combustion by turbulence or agitation of the gases in the furnace.

Ample heating surface exposed to the combustion chamber and high combustion temperature increase the heat transmitted by direct radiation, the importance of which is increasingly recognised.

As regards that part of the heating surface which receives heat by contact with the gases, the area required depends largely on the speed of the gas flow, high speeds resulting in high transmission rates. Restricted gas passages, however, while they lead to high gas speeds, are apt to be troublesome to keep free from deposit, and also require more draught (and hence usually the consumption of power for driving fans).

The tank type of boiler, such as the Lancashire or the cylindrical marine, has the advantage that the large amount of hot water contained enables it to respond quickly to sudden increases in demand for steam.

The Lancashire type is relatively free from breakdowns, the wear and tear are low, so that maintenance is cheap, it is easy to operate with semi-skilled labour, and is better suited than water-tube boilers to deal with impure feed water.

For burning low-grade fuels the water-tube boiler has advantages on account of its large brick-lined combustion chamber and adaptability for fitting with mechanical stokers and ash handling plant. The water-tube boiler can be constructed for very high pressures.

Boiler Output.

The steam generated per hour depends on the amount of fuel that can be properly burned on the grate per hour, and on the extent and efficiency of the heating surface.

For a particular type of boiler fuel, and draught, the steam-raising capacity is thus proportional to the grate area, though it is obvious that by control of the stoking, and particularly of the draught, the rate of combustion, and hence also the steam generated per hour, may be varied very widely.

Rate of Combustion and Draught.

With natural or chimney draught the air pressure at the grate depends on the height of the chimney, the temperature of the gases in the chimney, and the lay out of the flues. A typical figure is 0·65 in. of water per 100 ft. of chimney height, above the grate. The effective draught at the grate for a Lancashire boiler battery with economiser will be about one-third of this figure, and rather less for a water-tube boiler installation with economiser.

The coal burnt per hour per square foot of grate will be about :—

20 lbs. average steam coal; 5-10 lbs. anthracite very thinly spread.

For other chimneys and draughts the rate of combustion increases not quite in proportion to height.

The draught at the base of the chimney is due to the difference of the weight of the column of hot gases in the chimney and the weight of a similar column of external air.

If t_1 = temperature of external air; t_2 = mean temperature of gases in chimney; h = height of chimney in feet; d = draught in inches of water, measured at foot of chimney; density of gases (of typical composition) at 32° F. and atmospheric pressure = ·084 lb. per cu. ft.; density of air = ·0807 lb. per cu. ft., then,

$$\text{Mean density of gases at chimney temperature} = \cdot 084 \times \frac{493}{t_2 + 460} = \frac{41 \cdot 4}{t_2 + 460};$$

$$\text{Density of external air} = \cdot 0807 \times \frac{493}{t_1 + 460} = \frac{39 \cdot 8}{t_1 + 460};$$

$$\text{Pressure difference at base of chimney in lbs. per sq. foot} = h\left(\frac{39 \cdot 8}{t_1 + 460} - \frac{41 \cdot 4}{t_2 + 460}\right);$$

or

$$d \text{ in inches of water gauge} = h\left(\frac{7 \cdot 64}{t_1 + 460} - \frac{7 \cdot 95}{t_2 + 460}\right).$$

This is the 'theoretical' draught. The actual available draught is less than the theoretic by that required to produce the velocity of flow of the gases and by that required to overcon friction in the flues, economiser, and chimney. The loss due to velocity (in inches w.g.)

$$= d_v = 0 \cdot 10 \times \text{density of gases} \times \text{pressure} \times \frac{V^2}{t_2 + 460}$$

$$= \text{for typical gases } 0 \cdot 123 \frac{V^2}{t_2 + 460}$$

where

V = velocity of gases in chimney.

The friction loss (in inches w.g.) in the chimney

$$= d_f = 0{\cdot}40 \times f \times \text{density} \times \text{pressure} \times \frac{V^2}{t_2 + 460} \times \frac{L}{D}$$

where

f = friction coefficient = 0·016 say;
L = length of gas path in feet;
D = diameter of chimney in feet;

$$\therefore \text{ friction loss } d_f = 0{\cdot}0079 \frac{V^2}{t_2 + 460} \frac{L}{D}$$

It is convenient to relate the losses in the chimney to the weight of gas flowing rather than to the velocity.

If W = rate of flow of gas in lbs. per sec., the velocity loss d_v becomes

$$d_v = 0{\cdot}000117 \frac{W^2 (t_2 + 460)}{D^4}$$

and the friction loss

$$d_f = 0{\cdot}0000075 \frac{W^2 (t_2 + 460)\, L}{D^5}$$

Example.—A boiler battery consists of six boilers with a grate area of 38 sq. ft. each. What will be the draught at the foot of a chimney 150 ft. high and 7 ft. diameter, when the rate of combustion is 25 lbs. per hour per sq. ft. of grate area and the mean chimney temperature is 600° F.?

The coal burned per hour is 6,700 lbs.

The flue gases will amount to about 19 lbs. per lb. coal, or 108,000 lbs. per hour = 30 lbs. per sec.

The 'theoretical draught' (with external air at 60° F.)

$$= 150 \left(\frac{7{\cdot}64}{520} - \frac{7{\cdot}95}{1060}\right) = 1{\cdot}08 \text{ inches w.g.}$$

$$\text{Loss due to velocity} = 0{\cdot}000117 \times \frac{30^2 \times 1060}{7^4}$$

$$= 0{\cdot}046 \text{ inches w.g.}$$

$$\text{Loss due to friction} = 0{\cdot}0000075 \times \frac{30^2 \times 1060 \times 150}{7^5}$$

$$= 0{\cdot}064 \text{ inches w.g.}$$

$\therefore$ available draught at foot of chimney

$$= 1{\cdot}08 - (0{\cdot}046 + 0{\cdot}064)$$
$$= 0{\cdot}97 \text{ inch w.g.}$$

From this, the friction losses at flues, economiser (if any) and dampers must be deducted in order to find the draught at the boiler furnaces. Note, in the above example, if there were an economiser, the chimney temperature would be lower than 600° F., and hence the 'theoretical draught' itself would be less. The economiser thus reduces draught both by reducing chimney temperature and by its additional frictional resistance.

Effect of Altitude on Draught.

At high altitudes, the barometric height is less than at sea-level, and hence the density of the atmosphere is less. Hence also the 'theoretical draught' of a given chimney is reduced.

In order to obtain the same draught the height of the chimney must be increased.

The approximate ratio of the height required to the height required at sea-level is given in the following table:

Altitude above sea-level (ft.)	500	1,000	1,500	2,000	3,000	4,000
Ratio of heights	1·02	1·04	1·06	1·08	1·12	1·16

The diameter of the chimney at altitudes should also be increased by about 1½ per cent. for each 1,000 ft. of altitude.

Draught and Rate of Combustion.

Even if the draught at the grate is accurately known, this alone does not fix the rate of combustion, which is influenced by the kind of fuel and thickness of fire; the following tables, due to W. S. Hutton, must therefore be regarded as approximate only.

RATE OF COMBUSTION FOR DIFFERENT DRAUGHT PRESSURES.

Height of Chimney above Grate, in Feet.	Total Draught Pressure, in Inches of Water.	Rate of Combustion, in Pounds per Square Foot of Grate per Hour.	Height of Chimney above Grate, in Feet.	Total Draught Pressure, in Inches of Water.	Rate of Combustion, in Pounds per Square Foot of Grate per Hour.
25	·182	10	130	·948	30
50	·364	16	140	1·029	34
60	·437	17	150	1·095	40
70	·512	18	180	1·313	50
80	·583	19	200	1·459	60
90	·657	20	225	1·641	70
100	·729	22	250	1·825	80
110	·802	24	300	2·189	90
120	·875	27	400	2·553	112

TOTAL DRAUGHT REQUIRED FOR EFFICIENT COMBUSTION OF DIFFERENT KINDS OF FUEL.

Fuel.	Total Draught, in Inches of Water.	Fuel.	Total Draught, in Inches of Water.
Straw	0·20	Slack, very small	0·7 to 1·1
Wood	0·30	Coal-dust	0·8 to 1·1
Sawdust	0·35	Semi-anthracite coal	0·9 to 1·2
Peat, light	0·40	Mixture of breeze and slack	1·0 to 1·3
Peat, heavy	0·50	Anthracite, round	1·2 to 1·4
Sawdust, mixed with small coal	0·60	Mixture of breeze and coal-dust	1·2 to 1·5
Steam coal, round	0·4 to 0·7	Anthracite slack	1·3 to 1·8
Slack, ordinary	0·6 to 0·9		

In hand-fired plants, using coal for fuel, the rate of combustion should not be permitted to fall below 15 lbs. per sq. ft. of grate surface per hour. With stokers the rate of combustion may be as high as the design of the plant will permit. When firing with fine steam-size coal, the rate should not be less than 10 lbs. per sq. ft. of grate area per hour.

A typical working figure for the rate of combustion in stationary boilers with good natural or moderate assisted draught is 25 lbs. coal per hour per sq. ft. of grate area. For locomotives the rate is about 60 to 70, but may rise to 200.

USE OF DRAUGHT GAUGES ON STEAM BOILERS.

(*Chas. F. Wade, A.M.I.Mech.E., A.M.I.E.E.*)

The weight of oxygen or of air required to produce a given number of B.Th.U., using almost any fuel, is approximately constant, so that a measure of the air supplied to a boiler furnace is a good guide to the amount of fuel being consumed. If, therefore, the boiler is fitted with a steam flow indicator or meter as a measure of the heat transmission taking place, there will be a constant relation between air and steam flow under all conditions of steaming rate for a given efficiency, so that by careful initial tests of the waste gases under best conditions of operation this relation can be established once for all. Air flow may be gauged either by the difference in reading of two separate simple draught gauges connected sufficiently far apart in the path of the gas travel to obtain a large enough difference in air pressure or, preferably, a differential draught gauge may be connected across the two points; so long as the boiler and baffling, etc., remain in good condition the reading of such a gauge will provide a measure of the gas and air flow. The draught scale may with advantage have a second scale added giving the rate of steam flow corresponding to the most efficient conditions for the amount of pressure difference indicated and as established by the preliminary tests of the waste gas composition. Deterioration in the physical state of the boiler and its settings will be shown by inability to maintain the correct relation of steam and air flow, and the cause of the irregularity may be deduced from readings of the temperature of the waste gases.

KEEPS THE OIL IN
LANGITE joint washers, having an extraordinary degree of resilience, plus the outstanding advantage of being unaffected by oils and spirits, solve the problem of retaining oil.
Langite is used for joint washers on marine engines, motor car and lorry engines, gear-boxes, axles and hubs; for petrol tank joints on aircraft, and for other important uses, and is obtainable in any shape, size or thickness.
As an oil retainer for bearings it is most effective, having the necessary texture and resilience.

ESTABLISHED 1850

F .1609

A single draught gauge connected to one point of the gas circuit affords no indication of efficiency of combustion by itself, as a similar reading may be obtained under very widely differing conditions of fire thickness, initial draught, physical state, relation of forced to induced draught, etc.; thus mere working to a given reading on a simple draught gauge will inevitably lead to serious inefficiency from time to time.

Plain **U** tube gauges are not sufficiently sensitive to obtain close readings, and in addition cannot be arranged to give bold and distinct indications. Inclined tube gauges are much to be preferred, as each inch of height of liquid may be extended over a much longer scale. Open-scale, dial-type instruments are best of all, as they can be arranged to give a reading which can be observed clearly at a considerable distance, which cannot be done with any existing form of liquid column gauge.

Transmission of Heat in Boilers.

The transfer of the heat developed by the combustion of the fuel in the furnace to the water in the boiler takes place in two ways: (1) by radiation from the incandescent fuel and the hot gases; and (2) by convection and conduction—i.e. conduction through the materials in the path of the heat flow and by the contact of the gases and water with the metal separating them.

The transmission of heat to that part of the heating surface which is directly exposed to the fire is practically entirely by radiation, and that to the remainder of the heating surface practically entirely by convection.

Transmission by Radiation.

The heat transmitted by direct radiation in most boilers is strikingly large, so that the fire-box surface is much the most powerful evaporating surface.

The amount of heat radiated from a fire of temperature T_1 (° F. absolute) to the fire-box surface at T_2 is

$$1{,}600 \times \frac{T_1^4 - T_2^4}{1{,}000^4} \text{ B.Th.U. per hour per sq. ft.}$$

or practically, since T_2^4 is always negligible in comparison with T_1^4,

$$\text{Radiant heat} = 1{,}600 \left(\frac{T_1}{1{,}000}\right)^4.$$

Whether the radiating surface to be taken into account in calculating the total heat radiated is the grate area, or a larger amount, is debatable. The formula indicates, however, the importance of the direct heating surface, and also the importance of high combustion temperature for high rates of transmission.

Transmission through Plates or Tubes.

The transmission of heat from a fluid to another fluid on the other side of a metal tube depends on a large number of factors, including, as well as the area of tube surface and the temperatures, the velocities of the fluids, the diameter of the tube, and the nature of the fluids and of the tube surfaces. The change of temperature of the fluid passing through the tube is, of course, itself dependent on the factors named, so that the factors are not all independent. Differences of conductivity and thickness of the metals of the tube are negligible, the resistance to the passage of heat through the metal being a very small portion of the total resistance from fluid to fluid.

The coefficient of heat transmission is the number of heat units transmitted per unit time per unit area per degree of mean temperature difference (see p. 1877, and for determination of mean temperature difference see p. 1878).

For the conditions prevailing in the tubes of fire tube boilers, such as boilers of the locomotive type, waste-heat boilers, and air heaters, that is, where the current of hot gas—and for an air heater, the current of air being heated—is along the tubes, the coefficient of heat transmission can be related approximately to $\frac{w}{a}$, where w is the rate of gas flow in lbs. per sec., and a the cross section of the gas path in sq. ft. The results of investigations on different boilers vary widely, but for values of $\frac{w}{a}$ between 1 and 4, mean values of the transmission coefficient h are given by the equation $h = 0{\cdot}00077 \frac{w}{a} + 0{\cdot}00085$, where h = B.Th.U. transmitted per second per sq. ft. of heating surface per degree F. of temperature difference *between the gas and the metal.*

If, as in a boiler, one side of the tube metal is in contact with water, the temperature difference between metal and water is negligible compared with that between gas and metal, and in this case the temperature difference between gas and water may be used instead of that between gas and metal.

When both the substances separated by the tube wall are gaseous, the temperature differences on *each* side of the tube must be considered, or else the overall coefficient of transmission calculated.

The procedure that may be adopted is illustrated by the following examples:

Example 1.—A tubular boiler, in which the gases pass through the tubes at the rate $\frac{w}{a} = 2$, temperature of water (and of steam) = 350° F., gas temperatures 1,000° F. at inlet to 450° F. at outlet.

Mean temperature difference (M.T.D.) between gas and water

$$= \frac{(1{,}000 - 350) - (450 - 350)}{\log_e \frac{1{,}000 - 350}{450 - 350}} = 294.$$

This may also be taken as the M.T.D. between the gas and the tube metal.

Coefficient $h = 0{\cdot}00077 \times 2 + 0{\cdot}00085$
$= 0{\cdot}00239$, say 0·0024 B.Th.U. per sec. per sq. ft. per ° F.

$\therefore$ heat transmission rate $= 0{\cdot}0024 \times 294 = 0{\cdot}706$ B.Th.U. per sec. per sq. ft. (the heating surface being measured on the *gas* side of the tube).

If the tube is 2 ins. internal diameter, $a = 3{\cdot}14$ sq. ins. $= 0{\cdot}0218$ sq. ft.

$$\therefore \quad w = \frac{w}{a} \times a = 2 \times 0{\cdot}0218 = 0{\cdot}0436 \text{ lbs. per sec.}$$

Taking 0·25 as the mean specific heat of the gases, the heat given up in each tube
$= 0{\cdot}0436 \times 0{\cdot}25 \times (1{,}000 - 450) = 6$ B.Th.U. per sec.

$$\therefore \text{ tube surface required (internal)} = \frac{6}{0{\cdot}706} = 8{\cdot}5 \text{ sq. ft.}$$

$$\therefore \quad \text{tube length} = \frac{\text{surface}}{\text{perimeter}} = \frac{8{\cdot}5 \times 12}{6{\cdot}28} = 16{\cdot}2 \text{ ft.}$$

Evaporation (from and at 212° F.) per tube

$$= \frac{6 \times 3{,}600 \text{ (B.Th.U. per hour)}}{970 \text{ (B.Th.U. per lb. steam)}} = 22{\cdot}2 \text{ lbs. steam per hour.}$$

$\therefore$ for 2,000 lbs. steam per hour

Number of tubes required = 90
Total tube heating surface = 765 sq. ft.
Evaporation per sq. ft. of heating surface = 2·62 lbs. per hour (from and at 212° F.).

Example 2.—A tubular air heater, with tubes 2 ins. internal and 2¼ ins. external diameter; gas flowing inside tubes, air flowing in counter current direction outside tubes: $\frac{w}{a}$ for gas = 2; $\frac{w}{a}$ for air = 1·86; gas temperatures 700° F. and 450° F. at inlet and outlet; air temperatures 60° F. and 334° F.

h_g = coefficient of heat transmission on gas side = 0·0024.
h_a = do. on air side = 0·00228.

Mean temperature difference between gas and air

$$= \frac{(700 - 334) - (450 - 60)}{\log_e \frac{700 - 334}{450 - 60}} = 378.$$

It would be incorrect to take either h_g or h_a multiplied by 378 as the heat flow per sq. ft. per sec., since h_g and h_a refer respectively to the transmission between gas and *metal*, and *metal* and air only.

It can be shown that the mean temperature difference (M.T.D.) between gas and metal

$$= \text{M.T.D. between gas and air} \times \frac{1}{1 + \frac{h_g \times A_g}{h_a \times A_a}}$$

where A_g, A_a are the metal surfaces exposed to gas and air respectively.

In the example, $\frac{Ag}{Aa} = \frac{\text{internal diameter of tube}}{\text{external diameter of tube}} = \frac{2}{2 \cdot 25}$

$$\therefore \text{ M.T.D. gas to metal} = 378 \frac{1}{1 + \frac{0 \cdot 0024 \times 2}{0 \cdot 00228 \times 2 \cdot 25}} = 195 \cdot 3$$

$$\text{Similarly, M.T.D. metal to air} = 378 \frac{1}{1 + \frac{0 \cdot 00228 \times 2 \cdot 25}{0 \cdot 0024 \times 2}} = 182 \cdot 7$$

$\therefore$ heat transmitted per sec. $= 0 \cdot 0024 \times 195 \cdot 3$ B.Th.U. per sq. ft. of surface exposed to gas $= 0 \cdot 469$ B.Th.U. per sq. ft.

Also heat transmitted per sec. $= 0 \cdot 00228 \times 182 \cdot 7 = 0 \cdot 416$ B.Th.U. per sq. ft. of surface exposed to air.

These heat transmission rates must be inversely proportional to the areas on the gas and air sides, *i.e.* $\frac{0 \cdot 469}{0 \cdot 416}$ should be $\frac{2 \cdot 25}{2 \cdot 00}$, which is fulfilled very closely.

The length of tube required may be calculated as follows:

Rate of flow of gas in tube $= \frac{w}{a} \times$ area of tube

$$= 2 \times \frac{3 \cdot 1416}{144} = 0 \cdot 0436 \text{ lbs. per sec.}$$

Specific heat of gas $= 0 \cdot 25$.

$\therefore$ heat given up by gas in tube

$$= 0 \cdot 0436 \times 0 \cdot 25 \times (700 - 450) \text{ B.Th.U. per sec.}$$
$$= 2 \cdot 725 \text{ B.Th.U. per sec.}$$

$\therefore$ heating surface required (on gas side) $= \frac{2 \cdot 725}{0 \cdot 469} = 5 \cdot 81$ sq. ft.

Internal perimeter of tube $= 3 \cdot 1416 \times 2 = 6 \cdot 283$ in. $= 0 \cdot 5236$ ft.

$\therefore$ tube length $= \frac{5 \cdot 81}{0 \cdot 5236}$ ft. $= 11 \cdot 1$ ft.

The temperature differences are the chief factors in determining the length of tube (for usual values of $\frac{w}{a}$).

The number of tubes is determined from the total gas flow compared with the flo w per tube.

Thus if the gas flow is 4·4 lbs. per sec., the number of tubes for the above example would be $4 \cdot 4 \div 0 \cdot 0436 =$ say 100.

Example 3.—An alternative method of finding the heat transmission rates in the previous example is as follows:

If the overall coefficient of heat transmission from gas to air (neglecting the relatively small resistance of the metal) $= H$,

then $$\frac{1}{H} = \text{resistance to heat flow}$$

$$= \frac{1}{ha} + \frac{1}{hg} = \frac{1}{0 \cdot 0024} + \frac{1}{0 \cdot 00228}$$

therefore $$H = 0 \cdot 00117.$$

The overall mean temperature difference is 378°.

$\therefore$ rate of heat transmission

$$= 0 \cdot 00117 \times 378 \text{ B.Th.U. per sec. per sq. ft. of mean area}$$
$$= 0 \cdot 443 \text{ B.Th.U. per sec. per sq. ft. of mean area.}$$

The ratio of the areas on the gas and air sides is 2 : 2·25, or the areas are respectively 6 per cent. below and above the mean area.

The transmission rates are thus $0 \cdot 443 (1 - 0 \cdot 06) = 0 \cdot 416$ and $0 \cdot 443 (1 + 0 \cdot 06) = 0 \cdot 469$ B.Th.U. per sec. per sq. ft. of the respective areas, agreeing with the former calculation.

General Remarks on Tubular Heaters.

For a given range of temperatures, and a given value of $\frac{w}{a}$, the required tube length is proportional to tube diameter.

Hence if the length for a particular diameter has been calculated, the lengths for other diameters can be very readily found.

The tube length is *not* proportional to the drop of temperature of the heating medium; the extra tube length for each additional ten degrees say of temperature reduction at the outlet end becomes successively greater. Thus, if in a waste heat boiler, with water at 350° F., and initial gas temperature 1,000° F., the tube length is 12·2 ft. for outlet temperature 450° F., it will be 13·7 ft. for 430° F., and 15·5 ft. for 410° F. (the rate $w \div a$ and the diameter remaining the same).

The loss of pressure in the tubes, in inches of water gauge, may be taken as approximately

$$\left\{ 0{\cdot}0000216 \frac{l}{d} T_m + 0{\cdot}000075 \left(\frac{T_1}{2} + T_2 \right) \right\} \left(\frac{w}{a} \right)^2$$

where

l = tube length in ft.;

d = internal diameter of tube in ins.;

T_m = mean gas temperature, ° F. absolute $= \frac{T_1 + T_2}{2}$;

T_1 = inlet gas temperature, ° F. absolute;

T_2 = outlet gas temperature, ° F. absolute;

$\frac{w}{a}$ = lbs. of gas per sec. ÷ area of section of tube in sq. ft.

In this formula, the pressure of the gas is assumed to be atmospheric within a few ins. water gauge.

Fry's Empirical Formula.

In the case of boiler tubes with flue gases passing through them, the change of temperature of the gases, and thus also the heat transferred, can be calculated from the following equation (Lawford H. Fry, *Engineering*, Aug. 27, 1920):—

$$\text{lolog.} \frac{T_1}{t} - \text{lolog.} \frac{T_2}{t} = Mx \quad . \quad . \quad . \quad (1),$$

in which T_1, T_2 are the mean flue gas temperatures, ° F. absolute, at two sections of the tube x feet apart, t the mean temperature (absolute) of the tube wall, and 'lolog.' means 'logarithm of the logarithm.'

M is given by $\log. M = B - m \log. \frac{W}{p}$. (2) $\log. (B + 1{\cdot}3) = 1{\cdot}71 - 0{\cdot}54 \log. d$ . . (3)

$$\log. m = 1{\cdot}36 + 0{\cdot}37 \log. d \quad . \quad . \quad . \quad (4)$$

where,

d = internal diameter of tube in inches; p = perimeter of tube $(= d \times 3{\cdot}1416)$; W = rate of flow of gas in lbs. per hour.

Having determined the fall of temperature of the gases from the above, the heat given up —*i.e.* the heat transferred—is equal to

$$W \times (T_1 - T_2) \times \text{mean specific heat of gases.}$$

The following table gives the values of M for a number of tube diameters and rates of flow. These values may be used directly in equation (1).

Values of M.

d inches.	W in lbs. per hour.				
	100	200	400	800	1,600
0·5	0·133	0·117	0·104	0·092	0·081
1·0	0·074	0·063	0·054	0·046	0·039
2·0	0·050	0·040	0·033	0·027	0·022
4·0	0·040	0·030	0·023	0·018	0·014
8·0	0·037	0·026	0·019	0·013	0·009

EXAMPLES.

(1) To find fall of temperature in flue tube 2 ins. diameter and 12 ft. long, with rate of gas flow of 400 lbs. per hour, boiler pressure 180 lbs. per sq. in., and temperature of gases 2,000° F. at entrance of tubes.

The temperature of the metal of the tube is nearly that of the water in the boiler—i.e. nearly that of steam at 180 lbs. per sq. in.; thus $t = 380°$ F., about. (Slight differences in t have very little influence as a rule.)

From the table, for 2-in. tube, and W = 400 lbs. per hour, M = 0·033

$$\therefore \text{ lolog. } \frac{2{,}000 + 460}{380 + 460} - \text{lolog. } \frac{T_2}{380 + 460} = 0{\cdot}033 \times 12$$

$$\therefore \text{ lolog. } \frac{T_2}{840} = \bar{1}{\cdot}273;$$

$$\therefore \text{ log. } \frac{T_2}{840} = 0{\cdot}1875.$$

$\therefore T_2 = 1{,}293°$ F. abs., or 833° F.

(2) To find the heat transferred.

The mean specific heat of flue gases at the temperature in question may be taken as 0·31. Then the heat transferred in B.Th.U. per hour

$$= 400 \times (2{,}000 - 833) \times 0{\cdot}31 = 145{,}000.$$

The tube surface is 6·29 sq. ft., and heat transferred per sq. ft. = 23,100 B.Th.U. per hour.

(3) To find length of tube required to reduce the gas temperature to 700° F., rate of flow and diameter being as before:

$$\text{lolog. } \frac{2{,}000 + 460}{380 + 460} - \text{lolog. } \frac{700 + 460}{380 + 460} = 0{\cdot}033 \times \text{length.}$$

From which, length = 15·8 ft.

GRAPHIC CALCULATION OF HEAT TRANSMISSION THROUGH BOILER TUBES.

Fig. 1 (p. 1614) replaces equations (2) (3) and (4), and gives directly, without calculation, the value of M for any given values of W and d, or if required the value of any one of the three quantities W, M, d when the other two are known. In Fig. 1 any straight line will cut the three scales graduated in terms of W, M, d at graduations which satisfy equations (2) (3) (4).

Fig. 2 enables equation (1) to be solved graphically. The values of $\frac{T_1}{t}$ and $\frac{T_2}{t}$ are marked on the two end scales and values of Mx on the middle scale. Any straight line cuts these scales at graduations which satisfy equation (1).

Example 1:—To find the length of flue necessary for a temperature drop from 2,000 deg. F. to 720 deg. F. in a half-inch flue, with a wall temperature of 380 deg. F. and where 100 lb. of gas are passing per hour.

In Fig. 1 draw a straight line joining the points W = 100 and $d = 0{\cdot}5$. This line cuts the M scale at the required value of M = 0·132.

Since

$$\frac{T_1}{t} = \frac{2000 + 460}{380 + 460} = 2{\cdot}93, \text{ and } \frac{T_2}{t} = \frac{720 + 460}{380 + 460} = 1{\cdot}41,$$

therefore a straight line drawn in Fig. 2 joining these graduations on the $\frac{T_1}{t}$ and $\frac{T_2}{t}$ scales, will cut the Mx scale, at the required value of Mx, which is seen to be 0·50. Therefore, since $M = 0{\cdot}132$, $x = \frac{0{\cdot}50}{0{\cdot}132} = 3{\cdot}78$ ft., *i.e.*, a flue 3·78 ft. in length will be required for the given temperature drop.

Example 2:—To find what drop in temperature will take place in a half-inch flue, 5 ft. in length, when 1,600 lb. of gas are passing per hour and the temperature of flue gas at entry is 2,000 deg. F., the flue wall temperature being 420 deg. F.

From Fig. 1, by joining W = 1,600 and $d = 0{\cdot}5$, we get M = 0·081, therefore,

$$Mx = 0{\cdot}405.$$

But $\frac{T_1}{t} = \frac{2{,}000 + 460}{420 + 401} = 2{\cdot}80$, therefore, joining $\frac{T_1}{t} = 2{\cdot}80$ and $Mx = 0{\cdot}405$, in Fig. 2, we get

$$\frac{T_2}{t} = 1{\cdot}50,$$

therefore,

$$T_2 = 1{\cdot}50 \times 881 = 1{,}322° \text{ C.} = 861° \text{ F.}$$

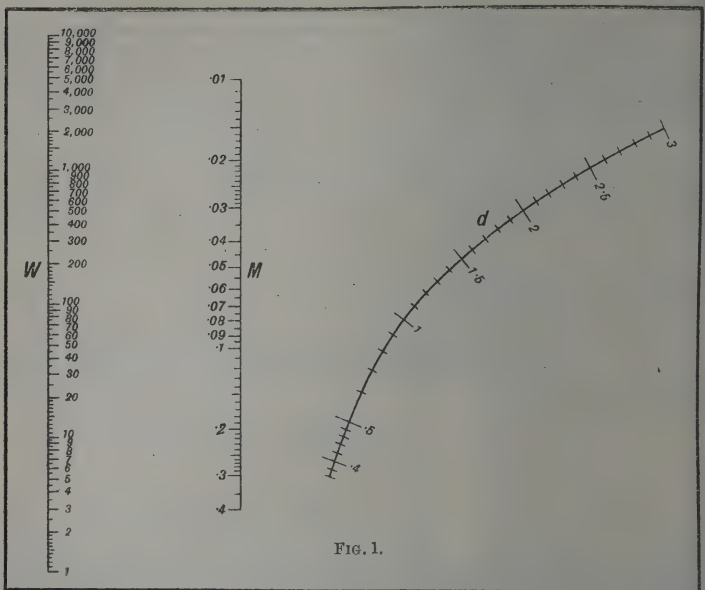

FIG. 1.

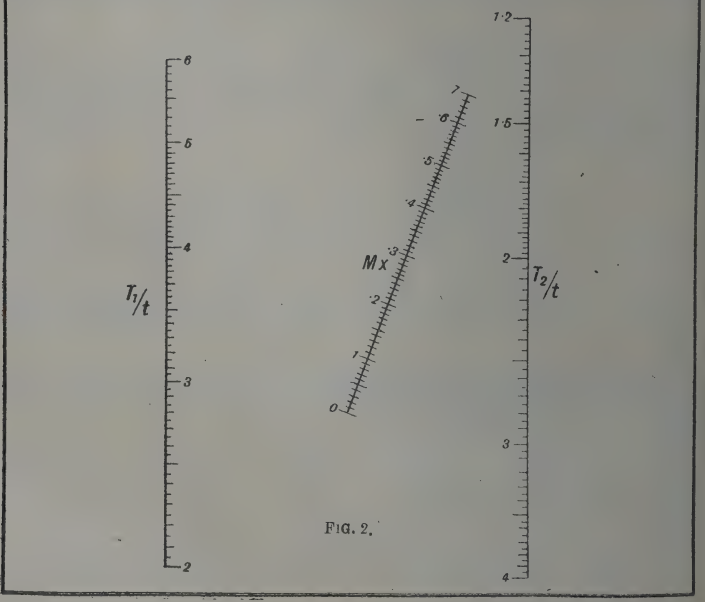

FIG. 2.

Actually, lines need not be drawn on the diagrams, as it is sufficient to lay a rule on the scales through the required points.

(A. J. V Umanski, M.Sc., *Engineering*, June 10, 1921.)

Very high rates of heat transmission have been attained in water-tube boilers when heavily forced. Spyer (Brit. Assoc., 1922) states that rates of working giving an average heat transmission of 24,000 B.Th.U. per hour per sq. ft. of heating surface have been attained on test without causing damage. With a single horizontally inclined tube a rate of 140,000 has been obtained experimentally.

Heating Surface.

The amount of heating surface required for efficient operation is much influenced by its arrangement, the proportion of it receiving heat by direct radiation, the velocity of flow of the gases through the flues or tubes, the circulation of the water, etc. While the ratio of heating surface to grate area thus varies widely, typical approximate values are as follows :—

Lancashire boiler	22–26
Water-tube	50–60
Water-tube, marine	35
Locomotive	60–70
Scotch boiler, marine	35–40
American tubular	50–80

The economiser surface should be about equal to the boiler surface for a Lancashire boiler and less, down to 50 per cent., for a water-tube boiler with ample heating surface.

For superheater surfaces see p. 1676.

As evidence of the effect of high gas speeds, cases are on record in which half the tubes in a tubular boiler have been plugged and yet the same total evaporation per hour obtained.

Recent Progress in Evaporation Rates.

Improvements in design which have raised the proportion of heat transferred by direct radiation have led to great increases in the rate of evaporation. This is illustrated by the following table relating to boilers installed at different dates at Bradford :—

Year.	Lbs. water evaporated per hour per sq. ft. heating surface.
1900	3·0
1902–11	3·25
1916	3·45
1926	6·0
1926 (on order)	12·0

Still higher rates have been achieved ; at Hell Gate Power Station, New York, boilers equipped with Murray fin-tube furnace walls have evaporated 14·7 lbs. per sq. ft. (see also p. 1620). It is reported that boilers are now being built for 69 lbs. per sq. ft., and that a still higher rate is claimed for a boiler at work in an industrial plant at Manchester.

(T. Roles, quoted in *Engineering*, June 3, 1927.)

Efficiency and Evaporation Rate.

The efficiency of a boiler depends not only upon good design, but is very much dependent upon good maintenance, cleanliness, prevention of air leakages in flues, and skilful stoking.

The actual evaporation in lbs. of steam per lb. of coal is a common, but somewhat unscientific, standard of efficiency. It obviously varies with the heat value of the coal, the steam pressure, and the superheat. When stated as the equivalent evaporation 'from and at 212° F.' it is a better basis, but is still dependent upon the quality of the coal. Thus, best Welsh coal will evaporate 25 per cent. more than an inferior slack with the same boiler efficiency. To convert actual evaporations into 'from and at 212' multiply by the B.Th.U. given to each lb. of water in heating, evaporating and superheating it, and divide by 970. Thus starting with water at 102° and superheating to 150° at 160 lbs. absolute, the B.Th.U. is 1214, so that the equivalent evaporation factor is 1·255.

If the calorific value of the coal is 11,800 B.Th.U. per lb., then an efficiency of 60 per cent. corresponds to an evaporation 'from and at 212°' of $\frac{11{,}800 \times \cdot 6}{970} = 7 \cdot 25$ lbs. water per lb. coal.

The evaporation per sq. ft. of heating surface depends on the fuel-combustion rate and the ratio of heating surface to grate area as well as on the efficiency.

Thus, in a Lancashire boiler burning 25 lbs. coal per hour per sq. ft. of grate, and having heating surface 25 times the grate area, if 7 lbs. water are evaporated per lb. coal, then the evaporation per sq. ft. of heating surface is 7 lbs. Similarly for a water-tube boiler 5 lbs., and for a locomotive 10 to 12 or more lbs. steam per sq. ft. heating surface are fair average figures.

By increasing the draught and thus increasing the rate of combustion, the output of the boiler can be much increased, but it should be noted that at high combustion rates the efficiency falls off.

For example, the series of trials of a Babcock and Wilcox boiler recorded on page 1660 show a maximum efficiency when burning 25 lbs. coal per sq. ft. of grate per hour. For rates of combustion between 30 and 70 these results correspond roughly to

$$w = \frac{78}{C} + 8{\cdot}3,$$

where C is the rate of combustion, and w the equivalent evaporation per lb. coal.

Typical figures for boilers in good condition, but without specially elaborate technical supervision, are :—

	Per cent.		Per cent.
Small cylindrical boiler, no economiser	50–55	Large water-tube boiler with economiser	70
Large cylindrical boiler with economiser	60–70	Do. highest class	70–80
Do. well fired and maintained	75	Locomotive boiler, moderately fired	65–70
Small water-tube boiler with economiser	50–60	Marine boiler, well fired	60–70

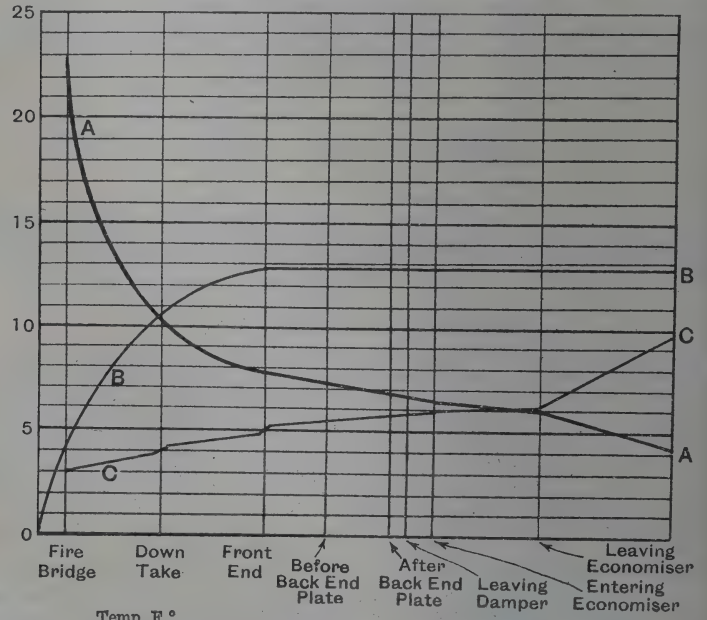
In the modern large power stations with large water-tube boilers and highly skilled technical supervision, efficiencies of 80 to 92 per cent. have been obtained.

That the efficiency of many boiler plants is much lower than the results which can be attained by greater care and skill in maintenance and supervision, is evidenced by the reports of Brownlie (p. 1617).

Maintenance of Boiler Efficiency.

(Chas. F. Wade, A.M.I.Mech.E., A.M.I.E.E.)

The arrangement advocated, and which has been adopted in several important modern power-stations with satisfactory results, consists in providing means of testing the CO_2 percentage, gas



Curve A = $\frac{\text{Temp. F.°}}{100}$; Curve B = CO_2%; Curve C = Draught ins. W.G. × 10.

FIG. 2A.

temperature, and draught pressure at regular intervals at a series of points situated at each consecutive stage in the gas travel through the boiler. Standard conditions being established with the newly overhauled boiler in as perfect a state of air-tightness, soundness of baffles, etc., with,

say, full rate of steaming, then readings are obtained of the three values mentioned, and are plotted to a suitable scale as three curves on a chart, as shewn in fig. 2A. The curves shown are ideal ones, and those obtained in practice will deviate more or less, even with a boiler in the best possible condition, both as to physical state and combustion conditions. The significance of the variations which may occur in the various curves for individual defects in state or operation are given in the following table, while combinations of two or more defects will produce modifications of the curves to correspond. The chart may be taken as an equivalent to the indicator diagram of a steam-engine, and is used to check the operation of the boiler and its state in an analagous manner.

INTERPRETATION OF WADE'S BOILER CONTROL CHARTS.

Fault.	I. Temperature Curve.	II. CO_2 Curve	III. Draught Curve.	Remarks.
Forcing boilers beyond economical capacity	High throughout	Low at A " " B Normal at D	*Induced and natural draught*—high throughout *Forced draught*—low throughout	
Over-heavy firing beyond air capacity	A low B and D possibly high	High throughout CO present Smoke	High throughout

Efficiency of Steam-Boiler Plant.

(*Contributed by David Brownlie, B.Sc. Hons. (Lond.), F.C.S., A.M.I. Mech.E.*)

(1)

The following are the true average figures for the performance of 250 steam-boiler plants in 17 different industries, comprising 1,000 boilers with an annual coal bill of 2,166,000 tons. Each test, comprising a day test and a check test of one week, was carried out with the greatest care

on the plant as actually working from week to week all the year round. Nearly 2,000 boiler plants were inspected and it was found that all were being worked on the same general lines—that is to say, these average figures apply to the burning of 75–100 million tons of coal burnt per annum in Great Britain for steam generation :—

AVERAGE WORKING FIGURES OF 250 TYPICAL BOILER PLANTS.

TESTS.

Average of 250 *Typical Boiler Plants.*

(A) *Working Day's Test.*

Type of boiler	'Lancashire'	Water evaporated per sq. ft. of grate area per hour	137·4 lbs.
Number of boilers	4	Water evaporated per lb. of fuel	6·56 lbs.
Grate area	152·6 sq. ft.	Equivalent evaporation from and at 212° F., per lb. of fuel	7·46 lbs.
Duration of test	9·43 hours	Equivalent evaporation from and at 212° F., per 1,000,000 British thermal units	631·0 lbs.
Amount of fuel used	30,131·72 lbs.	Temperature of feed-water before economisers	116° F.
Analysis of fuel used :		Temperature of feed-water after economisers	193° F.
British thermal units	11,822	Percentage of fuel bill saved by economisers	7·1 per cent.
Ash	11·5 per cent.		
Fuel burnt per boiler per hour	798·8 lbs.		
Fuel burnt per sq. ft. of grate area per hour	20·9 lbs.		
Water evaporated	197,776·0 lbs.		
Water evaporated per boiler per hour	5,243 lbs.		

(B) *Long Check Test* (one week of 7 days).

Duration	167·5 hours	Water evaporated per lb. of fuel	6·42 lbs.
Amount of fuel used	128·25 tons		
Water evaporated	184,435·0 galls.		

DETAILS.

Draught in side flue	0·40 in. W.G.	Temperature of superheated steam	346·5° F.
Draught in main flue at exit of economisers or chimney base	0·80 in. W.G.	Steam or power used as auxiliary to the production of steam	2·4 per cent.
Temperature of flue gases before economisers	598° F.	Thermal efficiency :	
Temperature of flue gases after economisers	478° F.	(A) Net working efficiency complete, after deducting 2·4 per cent. steam or power used as auxiliary to the production of steam	60·09 per cent.
Percentage of CO_2 in flue gases from side flue of boilers by means of combustion recorder	7·6 per cent.	(B) Boilers only	56·71 ,,
Steam pressure :		(C) Economisers only	4·35 ,,
Pounds per sq. in. (gauge)	89	(D) Superheaters only	0·51 ,,
Pounds per sq. in. (absolute)	104		
Temperature of saturation of steam	330·5° F.		

The installations from which the above average is derived comprise all sizes of plants with annual coal bills of from 750 tons to 70,000 tons ; whilst the average working pressure varied from 12 lbs. to 200 lbs. per sq. in. The fuels used were of every possible description, from the highest qualities of washed nuts, beans, peas, and fine slack, and large and small screened coal, down to interior fuels of all qualities, including refuse coal mixed with shale, pit sweepings, washer settlings, etc., as well as coke and coke breeze.

The 250 plants had a total of 1,000 boilers, comprising 935 'Lancashire' boilers, 36 modern 'tubular' boilers, 17 'egg-ended' boilers, 6 'Cornish' boilers, 1 'marine' boiler, 2 'vertical' boilers, and 3 'patent' boilers. The plants varied in size from one small 'vertical' boiler to 35 'Lancashire' boilers, 30 ft. by 8 ft.

The total grate area of the 250 boilers was 38,158·6 sq. ft., corresponding to 152·6 sq. ft. per plant, or 38·1 sq. ft. per boiler, which, on the assumption that all the boilers were 'Lancashire,' would give an average grate-area length of approximately 6 ft.

The average figure shows 20·9 lbs. of fuel per square foot of grate area per hour, referring to the average amount burnt per hour per working day, and not to the amount for any particular hour. This figure is considerably below what is possible on a boiler plant run on modern lines which would give something like 25 lbs. to 30 lbs. per square foot grate area per hour with the average quality of fuel. The boiler plants of the country are working under very easy conditions

in this respect, and much more fuel could be burnt per boiler. Figures for fuel consumption depend very largely on the quality of the fuel. Thus a good quality washed coal of, say, 13,000 British thermal units and 7 per cent. to 8 per cent. ash could easily be burnt economically at the rate of 35 lbs. per square foot per hour, whereas purely refuse coals would only give about 15 lbs. Coke of good quality can be burnt at the rate of 22 lbs. per square foot grate area per hour and coke breeze about 15 lbs.

The average for the 250 plants shows 11,822 British thermal units and 11·5 per cent. ash, which includes almost every description of coal and coke varying in quality from 7,000 British thermal units to 14,000 British thermal units.

As regards coke, a good average sample of coke shows about 12,000 British thermal units to 12,500 British thermal units with 12 per cent. ash, whilst a good sample of coke breeze shows 9,000 British thermal units to 10,000 British thermal units and 15 per cent. to 20 per cent. ash. The great trouble with coke and coke breeze is the amount of moisture contained in them. Good samples should only contain about 5 per cent. and certainly not over 8 per cent. Many samples, however, contain regularly 20 per cent., which is a most serious matter from the point of view of economy.

In a well-managed plant with average quality of coal a 'Lancashire' boiler, 30 ft. by 8 ft., can evaporate easily 850 gallons per boiler per hour, an increase of 62 per cent. of steam output as compared with average figures.

(2)

The following are the figures for two separate industries, namely, collieries, and chemical works:—

(1) *Collieries.*—Representing average figures for the complete investigation of 100 boiler plants, 570 boilers, annual coal bill 1,250,000 tons.

(2) *Chemical Works.*—Representing average figures for the complete investigation of 60 boiler plants, 236 boilers; annual coal bill, 620,000 tons.

Essential Figures of the Tests.	100 Colliery Plants.	60 Chemical Works Plants.

Notes or Additional Data in connection with some of above tests.

No. 4.—The efficiency stated is evidently based on the *lower* calorific value of the coal.

No. 5.—The oil-fired Yarrow boiler was afterwards provided with an air heater, and about 5 per cent. additional efficiency was obtained, at an evaporation of 40,000 lbs. per hour. Air entering heater at 1110° F., leaving at 240° F. Gas entering at 556° F., leaving at 435° F. Furnace temperature, 2530° F. Suction before heater, $\frac{5}{16}$ in., after $\frac{7}{8}$ in. Air pressure before, 0, after $1\frac{1}{4}$ in. The combustion chamber volume was 2,790 cub. ft.

No. 7.—Boilers at Lake Shore Power Station, Cleveland, U.S.A. Each boiler has a water screen with 835 sq. ft. heating surface. Sixteen fuel burners. The tests quoted are from a series of twenty-four published in the journal of the Amer. Soc. Mec. Eng. (*Mechanical Engineering*), Jan. 1925, which show the efficiency and distribution of losses at a wide range of loads, and at starting and banking conditions.

No. 8.—Boilers at Hell Gate Power Station, New York, U.S.A. The tests shown are selected from a large series showing the performance at different rates of evaporation. The boiler-heating surface includes 460 sq. ft. of water-cooled side walls.

From the above table the losses of heat in a boiler plant may be assigned to their respective causes.

CONSTRUCTION OF BOILERS

Boiler Shells.

Mild steel is now almost invariably used for boiler shells. As a rule, in order to provide a margin for wear and tear, plates below $\frac{3}{8}$ in. thick should never be used.

The bending of plates should be done by rolls, and not by hammering. Rivet holes should be drilled and the rough edge removed by a countersinking tool.

Steel for Boilers.

The steel is usually required to be made by the open-hearth acid process. The tensile trength is about 26 to 30 tons per sq. in. for shell plates, and 24 to 28 tons per sq. in. for plates or furnaces, flue tubes, and endplates.

Strength of Boiler Shells.

let
P = working pressure in lbs. per sq. in.;
t = thickness of plate in inches;
D = diameter (internal) of boiler in inches;
E = efficiency of longitudinal joint—i.e. proportionate strength of joint to plate;
F = factor of safety;
f = tensile strength of plate in lbs. per sq. in.;

hen,

$$P = \frac{2Ef}{DF}, \text{ or } t = \frac{PDF}{2Ef}.$$

The factor of safety is usually between 4 and 6. Frequently rules are used in which the ife working stress is substituted for $\frac{f}{F}$ in the above.

For permissible values of f, F, or $\frac{f}{F}$, the rules of the Boiler Survey or Insurance Society con- rned should be consulted.

For 'Standard Conditions for Marine Boilers,' see page 1625.

The proportionate strength of joint to plate—i.e. the efficiency of the joint—depends upon he type of joint, and also on the pitch and diameter of the rivets, and thickness of plate.

Typical percentage figures for single riveted lap joints are 40 to 58; for double riveted lap 5 to 70; for double butt (a butt strap each side of the plate and double riveted) 72 to 77; for reble riveted butt, each alternate rivet in outer rows being omitted, 82 to 85.

For the method of calculating the efficiency of riveted joints, see page 1629.

There is a strong tendency now in favour of butt joints for the longitudinal seams, by which the circular form of the shell is maintained, and there is less liability to grooving. The butt strap also protects the joint from corrosion.

All longitudinal seams break joint, as it is termed—that is, the seam in one ring of plates comes opposite to the solid plate in the next ring.

The efficiency of a riveted joint depends on the combination of dimensions as well as on the type of the joint, and there is no fixed relation between efficiencies of the different types of joints. However, for strength and sizes of material used in present-day boiler construction, the relative efficiencies obtainable with different types of joints are approximately as follows: Single-riveted lap joints, 57 per cent.; double-riveted lap joints, 74 per cent.; butt and double-strap joint, double-riveted, 82 per cent.; butt and double-strap joint, triple-riveted, 87 per cent.; and butt and double-strap joints, quadruple-riveted, 94 per cent.

(*'Power,'* Feb. 22, 1927.)

Working Strength of Boiler Flues.

(*Modern Dimensions.*)

P = working pressure, in lbs. per sq. in.
D = diameter, in inches.
L = length, in ft., between seams or hoops.
t = thickness of plate, in inches.

$$P = \frac{806300t^{2\cdot19}}{D \times L} \div \sqrt{\frac{300}{L}} \quad (Harrison).$$

$$P = \frac{50t^2}{D\sqrt{L}} - \frac{D}{L} \quad (M.\ Longridge).$$

(t being in 32nds of an inch.)

$$P = \frac{6149t^2}{\sqrt{DL}} \quad (W.\ H.\ Booth).$$

$$P = \frac{48000t^{2\cdot3}}{D\sqrt{L}} \quad (W.\ H.\ Booth).$$

TABLE OF 2·19 POWER FROM ¼ TO ½ INCH.

Power, 2·19 . . .	·04802	·07829	·116715	·16358	·21915

Every case ought to be finally examined to see that the actual pressure on each square inch of section of plate must not exceed the safe crushing resistance of the material, or $P = 30000t \div Df$. This rule may need applying to test the cases of thick furnaces. The value of f is 3 to 4. The strength of flues can be indefinitely increased by the employment of flanged seams, or corrugations.

See also page 1629.

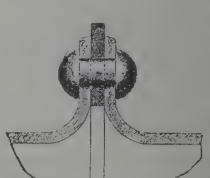

FIG. 3.—Flanged Seam.

The first form of joint in flue and furnace work was ordinary riveting, both transversely and longitudinally, but as weakness developed, the T iron hoop was tried; this, however, though strong, was found to be too rigid, and to lead to leakage in the seams. The flange out of the solid plate (fig. 3) was then designed by Daniel Adamson, and rapidly made its way to the front. The longitudinal joints are now welded, so that when the flange is adopted, no rivets whatever are exposed to the fire in the furnaces.

Pressures Required for Riveting and Flanging.

The pressure required for riveting is 75 to 125 tons per sq. in. of rivet area, preferably the lower value. Excessive pressure causes local deformation of the plate. The riveting pressure should be maintained for a short period, so that the rivet may cool down a little, otherwise the spring of the plate may stretch the rivet while it is still hot.

The pressure required for flanging boiler plates may be found from the formula:

$$F = \frac{2\cdot5(L \times t^2)}{L + 10},$$

where,

F = press load in tons; L = length run of flange in feet; t = thickness of plate in sixteenths of an inch. (*Mechanical World Year Book.*)

Welded Seams in Boilers.

The efficiency of welding depends essentially upon the skill and care of the workman who makes the weld; and in view of the uncertainty of the efficiency in practice as compared with tests, it is not advisable to use welds in parts of boilers subjected to tension, though parts in compression, such as furnaces and flue tubes, may be welded.

For particulars of oxy-acetylene and electric welding, see Section XL., Part II, p. 2747.

Many successful boiler repairs have been effected by welding, particularly in the making up of parts that have been wasted away, and the filling up of grooving.

Welded parts should be hydraulically tested to double the working pressure, the material at and around the weld being hammered while under test.

BOILER RULES AND REGULATIONS.

'Standard Conditions for the Design and Construction of Marine Boilers' have been recommended by a committee of representatives of the Board of Trade, British Corporation, Lloyd's Register, and Bureau Veritas. An abstract of the rules drawn up is given in the following pages. For boilers constructed to the requirements of a particular surveying body or boiler insurance company, the rules of the body concerned should be consulted.

Standard Conditions for the Design and Construction of Marine Boilers.*

(*Abstract.*)

MATERIALS OF CONSTRUCTION.

(*Based on British Standards.*)

Process of Manufacture.—Structural steel for marine boilers shall be made by the open-hearth process, acid or basic.

Freedom from Defects.—The finished material shall be free from cracks, surface flaws, and lamination. It shall also have a workmanlike finish, and must not have been hammer-dressed.†

Tensile Tests: Plates.—The tensile breaking strength of steel plates for shells and girders, determined from Standard test pieces, shall be between the limits of 28 tons and 35 tons per square inch, but a range of not more than 4 tons per square inch shall be permitted in any one case. For plates intended for flanging or welding, and for combustion chambers and furnaces, the tensile breaking strength shall be between the limits of 26 tons and 30 tons per square inch. The elongation, measured on a Standard test piece having a gauge length of 8 ins., shall be not less than 20 per cent. for material of $\frac{3}{4}$ in. in thickness and upwards, required to have a tensile breaking strength between the limits of 28 tons and 35 tons per square inch; and not less than 23 per cent. for material of $\frac{3}{4}$ in. in thickness and upwards, required to have a tensile breaking strength between the limits of 26 tons and 30 tons per square inch.

Stay Bars.—The tensile breaking strength of longitudinal stays shall be between the limits of 28 tons and 35 tons per square inch, with an elongation of not less than 20 per cent. measured on the Standard Test Piece B, but a range of not more than 4 tons per square inch shall be permitted in any one case. For steel bars for combustion chamber stays the tensile breaking strength shall be between the limits of 26 tons and 30 tons per square inch, with an elongation of not less than 23 per cent. measured on the Standard Test Piece B.

Where stay bars are tested on a gauge length of 4 times the diameter (Test Piece F), the elongation shall be 24 per cent. and 28 per cent. respectively.

The tensile breaking strength of angle and tee bars shall be between the limits of 28 and 32 tons per square inch, with an elongation of not less than 20 per cent. measured on the Standard Test Piece A.

For material under $\frac{3}{4}$ in. in thickness the elongation may be 3 per cent., but not more than 5 per cent., below the above-named elongations.

Wherever practicable the rolled surfaces shall be retained on two opposite sides of the test piece.

Rivet Bars.—The tensile breaking strength of rivet bars shall be between the limits of 26 tons and 30 tons per square inch of section, with an elongation of not less than 25 per cent. measured on the Standard Test Piece B or 30 per cent. measured on the Standard Test Piece F. The bars may be tested the full size as rolled.

Bend Tests: Cold Bends.—Test pieces shall be sheared lengthwise or crosswise from plates or bars, and shall not be less than $1\frac{1}{2}$ ins. wide, but for small bars the whole section may be used. For rivet bars bend tests are not required.

---

* Published by His Majesty's Stationery Office.

† The Board of Trade have more detailed instructions which they propose to retain.

Temper Bends.—The test pieces shall be similar to those used for cold bend tests. For temper bend tests the samples shall be heated to a blood-red colour and quenched in water at a temperature not exceeding 80° F. The colour shall be judged indoors in the shade.

In all cold bend tests, and in temper bend tests on samples 0·5 in. in thickness and above, the rough edge or arris caused by shearing may be removed by filing or grinding, and samples 1 in. in thickness and above may have the edges machined, but the test pieces shall receive no other preparation. The test pieces shall not be annealed unless the material from which they are cut is similarly annealed, in which case the test pieces shall be similarly and simultaneously treated with the material before testing.

For both cold and temper bends the test piece shall withstand, without fracture, being doubled over until the internal radius is equal to 1½ times the thickness of the test piece, and the sides are parallel.

For small sectional material these bend tests may be made from the flattened bar.

Bend tests may be made either by pressure or by blows.

Tests for Manufactured Rivets.—Rivets selected by the Inspector from the bulk shall withstand the following tests:—

(*a*) The rivet shanks are to be bent cold, and hammered until the two parts of the shank touch, without fracture on the outside of the bend.

(*b*) The rivet heads are to be flattened, while hot, in the usual manner, without cracking at the edges. The heads are to be flattened until their diameter is 2½ times the diameter of the shank.

FORMS OF BRITISH STANDARD TENSILE TEST PIECES.

For Plates and other Structural Material.

TEST PIECE A.

X.—For thicknesses over ⅝ths in.: Maximum width allowed = 1½ ins. Y.—For thicknesses ⅜ths in. to ⅝ths in. Maximum width allowed = 2 ins. Z.—For thicknesses under ⅜ths. in. Maximum width allowed = 2½ ins.

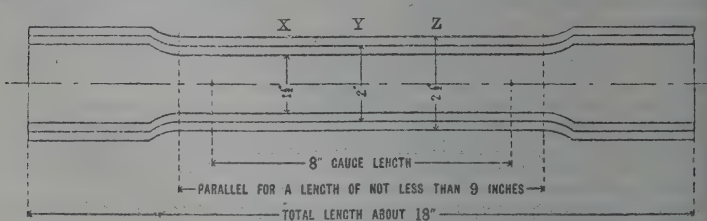

FIG. 4.

NOTE.—It will be observed that the widths given above, being maxima, do not exclude the use of the usual 1½ ins. by 8 ins. test pieces.

TEST PIECE B.

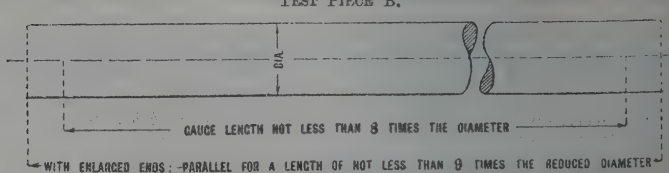

FIG. 5.

TEST PIECE F.

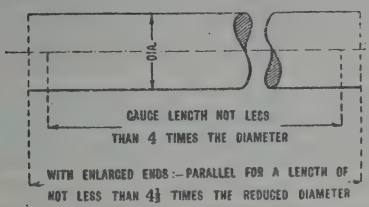

FIG. 6.

SPECIAL IRON FOR SCREW STAYS FOR COMBUSTION CHAMBERS.

In order that iron screw stays may be approved of the same size as would be required for mild steel, the iron must withstand the following tests:—

Tensile Tests.—The tensile breaking strength shall not be less than 21½ tons per square inch, with an elongation of not less than 25 per cent. measured on the Standard Test Piece B, or of 20 per cent. measured on the Standard Test Piece F.

Bend Tests.—Test pieces either of the bar as rolled, or turned down to 1 in. diameter, shall stand bending cold until the sides are parallel and the space between the two sides is not greater than the diameter of the test piece.

Diameters and Thickness of Plain and Stay Tubes.—The following table may be worked to:—

Outside Diameter in Inches.	Standard Thicknesses in L.S.G.				Suitable for Working Pressures of Lbs. per Square Inch.			
Inches.	A	B	C	D	A	B	C	D
2	—	11	10	9	—	155	215	300
2¼	11	10	9	8	140	190	260	315
2½	11	10	9	8	125	175	230	300
2¾	11	10	9	8	110	160	215	275
3	10	9	8	7	140	190	250	300
3¼	10	9	8	7	130	180	230	280
3½	10	9	8	7	120	165	215	260

The minimum thickness of stay tubes measured under the threads shall be ¼ in. for marginal stay tubes, and $\frac{4}{16}$ in. for other stay tubes.

Thickened Ends.—If stay tubes are required to have their thickness increased at the screwed ends, so that the thickness at the bottom of thread is practically the same as in the body of the tube, the thickening is to be attained by upsetting and not by any welding process, and the tubes are to be annealed after the upsetting.

Screwed Threads to be Continuous.—Stay tubes must be screwed at both ends with a continuous thread, which should not be finer than 10 threads per inch. It is desirable, however, that they should be screwed to the standard 9 threads per inch, therefore, after 30th June, 1921, this should be the rule.

MAIN BOILERS, CYLINDRICAL TYPE.

GENERAL CONDITIONS AS TO DESIGN, WORKMANSHIP, HYDRAULIC TEST, ETC.

In the design and construction of marine boilers the following conditions should be observed:—

Riveting of End Seams.—The riveting of the seams joining the end plates to the cylindrical shell shall be not less than 42 per cent. of that of the solid plate. Where the shell plates exceed ½ in. in thickness the seams connecting the shell plates to the end plates are to be double riveted.

Other Circumferential Seams.—The circumferential seam at or near the middle of the lengt of single-ended boilers should have a strength of joint not less than 60 per cent. of the solid plate The inner circumferential seams of double-ended boilers should have a strength of joint no less than 62 per cent. of the solid plate. In any case there shall be three rows of rivets whe single-ended boilers have shell plates over $1\frac{3}{8}$ ins. in thickness, and when double-ended boiler have shell plates over $1\frac{3}{8}$ ins. in thickness. Where the shell plates exceed $\frac{1}{2}$ in. in thickness the intermediate circumferential seams of double-ended boilers are to be at least double riveted

Welding and other Treatment of Plates.—No steel plates subject to a direct tensional stres are to be welded except where the weld is covered by a butt strap or straps. For small stean domes, by special permission where the welding is done by hammer and the plates do not exceed $\frac{1}{2}$ in. in thickness, the straps may be omitted. The strength shall, in such cases, be assume to be 50 per cent. of that of the solid plate. All steel plates which are welded, dished, flanged or locally heated, are to be afterwards efficiently annealed.

Butt Straps.—Butt straps must be cut from plates, and not from rolled strip.

Rivet Holes.—All rivet holes must be drilled 'fair,' and as far as possible they should b drilled in place. After drilling the plates the burrs should be removed and the faying surface of the plates cleaned, and the sharp outer edges of holes removed also.

Stays not to be Welded. Annealing of Fire-worked Stay Bars.—No steel stays are to be welded If plus threads are desired, the ends of the stay bars may be upset or the bars may be drawn down in the central portions from bars originally of the size of the ends. In either of these tw cases the bars must be subsequently annealed throughout.

In double-ended boilers the through longitudinal stays must be supported at or near th middle of their length.

Threads of Screw and other Stays.—All longitudinal stays and also screw stays should hav threads in accordance with the British Standard Specification, and true to pitch, viz. :—

After the 30th June, 1921, all screw stays $1\frac{1}{4}$ ins. in diameter and upwards should have threads per inch, and all stays 2 ins. in diameter and above passing through plates and secure by nuts on each side of the plate should have not more than 6 threads per inch.

Compensation Rings to Manholes.—Where the cylindrical shell is cut for a manhole, com pensation must be provided and must be such that the strength in way of the hole is not les than that required for the longitudinal joint.

Hydraulic Tests of New Boilers.—In all new boilers working at pressures up to 100 lbs. pe square inch the hydraulic test must be twice the working pressure. For boilers working a pressures greater than 100 lbs. per square inch the hydraulic test pressure must be $1\frac{1}{2}$ time the working pressure plus 50 lbs. per square inch.

RULES FOR DETERMINING THE WORKING PRESSURE TO BE ALLOWED ON VARIOUS PARTS OF CYLINDRICAL MARINE BOILERS.

Cylindrical Shells.

Formula for Working Pressure of the Shell.—For the cylindrical shells of steel marine boile the maximum working pressure (which is designated by W.P. and is in lbs. per square inch to be allowed shall be calculated from the following formula :—

Where the thickness of the shell plates does not exceed $1\frac{1}{4}$ ins.,

$$\text{W.P.} = \frac{(t - 2) \times S \times J}{C \times D}$$

Where the thickness of the shell plates exceeds $1\frac{1}{4}$ ins. and double butt straps are fitted,

$$\text{W.P.} = \frac{t \times S \times J}{2{\cdot}85 \times D}$$

where,

t is the thickness of the shell plates in 32nds of an inch,

S is the minimum tensile strength of the steel shell plates in tons per square inch,

J is the percentage of strength of the longitudinal seams calculated by the methods describe on page 1629.

C is a coefficient, which is 2·75 when the longitudinal seams are made with double butt straps; 2·83 when the longitudinal seams are made with lap joints and are treble riveted; 2·9 when they are made with lap joints and are double riveted; and 3·3 when they are made with lap joints and are single riveted.

D is the inside diameter of the outer strake of plating of the cylindrical shell measured in inches.

N.B.—The factor of safety must be in no case less than 4.

Methods of Calculating the Strength of Riveted Joints.—The percentage of strength of a riveted joint (J) is found from the following formulæ (I), (II), (III): (I) and (II) are applicable to any type of joint; (III) is applicable only to that type of joint in which the number of rivets in the inner rows is double that in the outer row. The lowest value given by the application of these formulæ is to be taken as the percentage of strength of the joint.

(I) Percentage of strength of plate at joint as compared with solid plate $= \dfrac{100\,(p-d)}{p}$

(II) Percentage of strength of rivets as compared with the solid plate $= \dfrac{100\,(S_2 \times a \times n \times C)}{S_1 \times p \times T}$

(III) Percentage of combined strength of the plate at the inner row of rivet holes and of the rivets in the outer row

$$= \frac{100\,(p-2d)}{p} + \frac{100\,(S_2 \times a \times C)}{S_1 \times p \times T},$$

where,

p = pitch of rivets at outer rows in inches;
d = diameter of rivet holes in inches;
a = sectional area of one rivet in square inches;
n = number of rivets which are fitted in the pitch p;
T = thickness of plate in inches:
C = 1·0 for rivets in single shear as in lap joints;
C = 1·875 for rivets in double shear as in double butt-strapped joints;
S_1 = minimum tensile strength of plates in tons per square inch;
S_2 = shearing strength of rivets, which is taken generally to be 23 tons per square inch, and may be 85 per cent. of the minimum tensile strength of the rivet bars.

Thickness of Butt Straps.—Where the longitudinal seams are fitted with double butt-strapped joints, the outer butt strap should have at least 0·625 of the strength of the plate, and should be of sufficient thickness to permit of efficient caulking of its outer edges. The inner butt strap should be $\frac{4}{32}$ in. thicker than this.

In cases where the number of rivets in the inner rows is double the number in the outer row, this will require the thickness of the outer strap to be

$$t = \frac{5 \times (p-d)}{8 \times (p-2d)} \times T,$$

and that of the inner strap to be at least

$$t_n = \frac{5 \times (p-d)}{8 \times (p-2d)} \times T + \tfrac{4}{32} \text{ in.}$$

Distances between rows of Rivets and between Rivets and Plate Edges.—In all cases the clear space between a rivet hole and the edge of a plate should not be less than the diameter of the rivet hole—i.e. the centre of the rivet hole should be at least $1\frac{1}{2}$ diameters distant from the edge of the plate.

In joints, whether lapped or fitted with butt straps, in which there are more than one row of rivets and in which there is an equal number of rivets in each row, the distance between the rows of rivets should be not less than $0{\cdot}33p + 0{\cdot}67d$, with zigzag riveting, or $2d$ with chain riveting.

In joints in which the number of rivets in the outer rows is one-half of the number in each of the inner rows, and in which the inner rows are chain riveted, the distance between outer rows and the next rows should be not less than $0{\cdot}33p + 0{\cdot}67d$ or $2d$, whichever is the greater, and the distance between the rows in which there are the full number of rivets should be not less than $2d$.

In joints in which the number of rivets in the outer rows is one-half of the number in each of the inner rows, and in which the inner rows are zigzag, the distance between the outer rows and the next rows should be not less than $0{\cdot}2p + 1{\cdot}15d$, and the distance between the rows in which there are the full number of rivets should be not less than $0{\cdot}165p + 0{\cdot}67d$.

In the above p is the pitch of the rivets in the outer rows.

Maximum Pitch of Rivets in Longitudinal Joints.—The maximum pitch of the rivets in th longitudinal joints of boiler shells is to be—

$$\text{Maximum pitch in inches} = C \times T + 1\tfrac{5}{8} \text{ ins.}$$

where T is the thickness of the plate in inches and C is a coefficient as given in the followin table:—

Number of Rivets per Pitch.	Coefficients for Lap Joints.	Coefficients for Double Butt-strapped Joints.
1	1·31	1·75
2	2·62	3·50
3	3·47	4·63
4	4·14	5·52
5	—	6·00

FURNACES.

Plain Furnaces.—The working pressure to be allowed on plain furnaces or furnace strengthened by Adamson or other joints, and on the cylindrical bottoms of combustion chambers is to be determined by the following formulæ, the least pressure obtained by either formul being taken:—

$$\text{W.P.} = \frac{C\,(t-1)^2}{(L+24)\times D}, \text{ or W.P.} = \frac{C_1}{D} \times [10\,(t-1) - L].$$

where D is the external diameter of the furnace or combustion chamber bottom in inches;

t is the thickness of the furnace plate in 32nds of an inch;

L is the length of the furnace or of combustion chamber bottom or the length betwee points of substantial support, in inches, measured from the centres of rive rows or from the commencement of flange curvature, whichever is applicable

C = 1,450 where the longitudinal seams are welded, and 1,300 where they are riveted

C_1 = 50 where the longitudinal seams are welded, and 45 where they are riveted.

W.P. = working pressure in lbs. per square inch.

Corrugated Furnaces.—The working pressure to be allowed on corrugated furnaces is to b determined by the following formula:—

$$\text{W.P.} = \frac{C\,(t-1)}{D},$$

where D is the external diameter measured at the bottom of the corrugations in inches;

t is the thickness of the furnace plate in 32nds of an inch, measured at the bottom o the corrugation or camber;

C is a coefficient which is 480 for the Fox, Morison, Deighton, Purves, and other simila furnaces, 510 for the Leeds Forge Bulb Suspension furnace.

N.B.—No furnace, plain or corrugated, should exceed $\frac{13}{16}$ in. in thickness.

FLAT PLATES SUPPORTED BY STAYS SECURED IN VARIOUS WAYS.

Flat Plates supported by Screwed Stays.—The working pressure to be allowed on flat plate supported by stays is to be calculated by the following formula:—

$$\text{W.P.} = \frac{(t-1)^2 \times C}{a^2 + b^2},$$

but if steel of less tensile strength than 26 tons per square inch is used the working pressur allowed shall be correspondingly reduced.

In this formula,

W.P. is the working pressure in lbs. per square inch;

t is the thickness of the flat plate in 32nds of an inch;

a is the distance apart of the rows of stays in inches;

b is the pitch of the stays in the rows in inches;

C is a coefficient which varies with the method of fixing the stays as follows:—

Where the plates are exposed to flame and the stays are screwed into the plate and thei ends are riveted over, C = 50.

Where the plates are not exposed to flame and the stays are screwed into the plate and their ends are riveted over, C = 57.

In these cases the thickness of he plate must be at least half the diameter of the stay required by the rule.

Where stay tubes are screwed into tube plates and expanded, C = 52. If they are fitted with nuts, C = 72.

Where the plates are exposed to flame and the stays are screwed into the plate and fitted with nuts on the outside, C = 75. Where the plates are not exposed to flame, C = 86.

Where the stays pass through the plates not exposed to flame and are fitted with nuts inside and outside, C = 96.

Where plates are stiffened by flanging, the inner radius of which is not greater than $2\frac{1}{2}$ times the thickness of the plate, for the support thus given C = 110 when the plates are not exposed to flame, and C = 96 where they are exposed to flame. The pitch is to be reckoned from the commencement of the curvature.

GIRDERS.

Girders Supporting Combustion Chamber Tops.—For girders supporting the tops of combustion chambers the following formula is to be used :—

$$\text{W.P.} = \frac{\text{C} \times d^2 \times t}{(\text{L}-\text{P}) \times \text{D} \times \text{L}} \times \frac{\text{S}}{28},$$

where,

d is the depth of the girder at centre in inches ;

t is the thickness of the girder at centre, when this is a forging, or the sum of the thicknesses of the plates when the girder is made of two plates, measured in 32nds inch ;

L is the length of the girder in inches, measured between the tube plate and back chamber plate inside, or between tube plates in chambers common to two opposite furnaces ;

P is the pitch of stays supported by the girder, in inches ;

D is the distance apart of the girders, centre to centre, in inches ;

S is the minimum tensile strength of the steel plates forming the girder, in tons per square inch. In the case of forged girders S is to be taken as 24 for iron and 28 for steel ;

C is a coefficient as follows :—

$$\text{C} = \frac{n}{n+1} \times 495,$$

when the number of stays in each girder is odd, and

$$= \frac{n+1}{n+2} \times 495,$$

when the number of stays in each girder is even, n being the number of stays to each girder.

STAYS.

Iron or Steel Screw Stays to Combustion Chambers.—For screw stays with threads not coarser than 9 threads per inch, made of steel or of special wrought iron tested to the requirements, the following formula is to be used :—

$$\text{W.P.} = \frac{(d - 0{\cdot}267)^2 \times 8{,}250}{a},$$

where,

d is the diameter of the stay over the thread in inches ;

a is the area in square inches supported by one stay.

But in no case must the stress exceed 9,000 lbs. per square inch of section.

Steel Longitudinal Stays.—For steel longitudinal stays with threads not coarser than 6 thread per inch, the working pressure is to be calculated from the following formula :—

$$\text{W.P.} = \frac{(d - 0{\cdot}340)^2 \times 9{,}500}{a} \times \frac{S}{28},$$

where d is the diameter of the stay over the thread in inches;

a is the area in square inches supported by one stay;

S is the minimum tensile strength of the steel in tons per square inch.

But in no case must the stress exceed 11,000 lbs. per square inch of section, when steel of minimum tensile strength of 28 tons per square inch is used.

In cases where longitudinal stays are made with enlarged ends, and the body of the stay smaller in diameter than at the bottom of the thread, and in cases where coarser threads tha 6 per inch are used, the working pressure is to be calculated from the following formula :—

$$\text{W.P.} = \frac{(d_1 - 0{\cdot}125)^2 \times 9{,}500}{a} + \frac{S}{28},$$

where d is the diameter of the stay at the bottom of the thread or at the smallest part the body.

Stay Tubes.—On stay tubes, whether of wrought iron or of lap-welded steel, a working stre of 7,500 lbs. per square inch of the net sectional area at the bottom of the thread is permitted.

Dished Ends (Convex Outside).—For ends of steam chests, etc., dished to partial spheric form, the following formula is to be used :—

$$\text{W.P.} = \frac{15 \times S\,(t - 1)}{R},$$

where

W.P. is the working presures in lbs. per square inch;

t the thickness in 32nds of an inch;

R the inner radius of curvature of the end in inches, which shall not exceed the diamet of shell;

S the minimum tensile strength of plates in tons per square inch.

Safety Valves.—At least two safety valves must be fitted to each boiler. They must l arranged so that the springs and valves are cased in, that the valves cannot be overloaded wh steam is up, that they can be lifted by easing gear, and turned round on their seats by han and in case of fracture of springs they cannot lift out of their seats.

The easing gear must be arranged to lift all the safety valves on a boiler together, and mu be workable from some accessible place free from steam danger.

All the safety valves of each boiler may be fitted in one chest, which must be separate fro any other valve chest and which must be connected direct to the boiler by a strong and st neck, the passage through which should have a cross-sectional area at least equal to one-h the aggregate area of the safety valves in the chest.

Each safety valve box shall have a means of draining it; the pipe shall lead to the bilge tank clear of the boiler.

Size of Safety Valves.—The minimum aggregate area of the safety valves of the ordina type in each boiler, whether coal-fired or oil-fired, and whether working under natural, force or induced draught, shall be found by the following formula :—

Aggregate area of safety valves in square inches

$$= \text{Total heating surface of boilers in square feet} \times \left(\frac{K}{p + 15}\right),$$

where p is the working pressure in lbs. per square inch.

For coal-fired boilers K is 1·25, for oil-fired boilers and boilers with closed stokehold forc draught K = 1·5.

Accumulation Test of Safety Valves.—All safety valves must be set to the required pressure under steam. During a test of 15 minutes with the stop valves closed, and under full firing conditions, the accumulation of pressure must not exceed 10 per cent. of the loaded pressure. During this test no more feed-water should be supplied than is necessary to maintain a safe working water level.

Superheater Safety Valves and Drains.—Where a superheater is fitted which can be shut off from the boiler it must have a separate safety valve fitted with easing gear, etc. The valve as regards construction must comply with the regulations for ordinary safety valves, but the easing gear may be fitted to be workable from the stokehold only.

The superheater must be fitted with a drain cock or valve to free it from water when necessary.

BRITISH STANDARD SPECIFICATION FOR CHARCOAL IRON LAPWELDED BOILER TUBES.*

(No. 43—1927.) (*Abstract.*)

1. The tubes shall be lapwelded and shall be made from genuine charcoal iron of the best ality. 2. The tubes shall be sound, clean, smooth and well finished, free from surface defects, st and longitudinal grooving, both internally and externally, and the ends shall be clean and uare. 3. The tubes shall be carefully annealed at both ends. 6. The tubes or strips cut from e tubes shall show a tensile strength between the limits of 19 and 24 tons per square inch clusive, with a contraction of area of the metal of not less than 45 per cent. 7. The tubes

* By permission of the British Engineering Standards Association.

shall stand bulging both hot and cold with a parallel drift (fig. 7) without showing either crack or flaw, until the diameter of the bulged end exceeds the original diameter of the tube by not less than 15 per cent. when tested hot and by not less than 10 per cent. when tested cold. 8. A piece

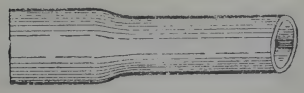

FIG. 7.

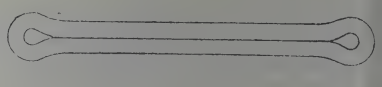

FIG. 8.

of tube 2 ins. long shall be placed on end and shall stand hammering down until it is reduced to 1⅛ in. high, without showing crack or flaw. 9. The tubes shall, when cold, stand flattening (fig. 8) without showing crack or flaw until the interior surfaces of the tubes meet. 10. Each tube shall be tested by an internal hydraulic pressure of at least 750 lbs. per sq. in., and any tubes failing to stand this test shall be rejected.

BRITISH STANDARD SPECIFICATION FOR COLD DRAWN WELDLESS STEEL TUBES FOR LOCOMOTIVE BOILERS.*

(No. 53—1927.) (*Abstract*).

Quality of Material.

1. The tubes shall be cold drawn and weldless, and shall be manufactured from steel of the best quality made by the Open-Hearth process. They shall not show on analysis more than 0·035 per cent. of sulphur or more than 0·030 per cent. of phosphorus. The manufacturer shall supply an analysis when required to do so.

Freedom from Defects.

2. The tubes shall be perfectly sound, clean, smooth, and well finished, free from surface defects, rust and longitudinal grooving, both internally and externally, and the ends shall be clean and square.

Annealing.

3. The tubes shall be carefully annealed throughout their length after the operation of drawing and the ends shall be carefully annealed after the process of enlarging or decreasing the diameter.

Permissible Variation in Weight.

4. The actual weight of each tube shall not differ from the calculated weight by more than 5 per cent. above or 2½ per cent. below the weight calculated from the specified dimensions allowing 489·6 lbs. per cubic foot of metal in the tubes.

Tensile Test.

6. The tubes or strips cut from the tubes shall, without further annealing, show a tensile strength of not less than 20 tons per sq. in. nor more than 26 tons per sq. in. with an elongation of not less than 28 per cent. in 8 ins. for tubes, and not less than 22 per cent. in 8 ins. for strips cut from the Tubes. If strips are cut for testing from tubes over 2¼ ins. diameter they may be annealed before testing.

Crushing down Test.

8. A piece of tube 2 ins. long shall be placed on end and shall, when cold, stand hammering down until it is reduced to 1⅛ ins. high, without showing either crack or flaw.

Flattening Test.

9. The tubes shall, when cold, stand flattening (fig. 8), without showing either crack or flaw until the interior surfaces of the tubes meet or, when the tubes are over 11 S.W.G. in thickness until the interior surfaces are brought to a distance apart equal to the thickness of the wall of the tube.

Hydraulic Test.

10. Every tube shall be tested by an internal hydraulic pressure of at least 1,000 lbs. per sq. in., and any tubes failing to stand this test shall be rejected.

* By permission of the British Engineering Standards Association.

TYPES OF BOILERS.

LANCASHIRE AND CORNISH BOILERS.

The distinction between these two general types is that the Cornish has one and the Lancashire two internal flues.

These boilers were originally made with iron plates, and had flat ends (often in two or three pieces), the flat surfaces being strengthened with rod and gusset stays.

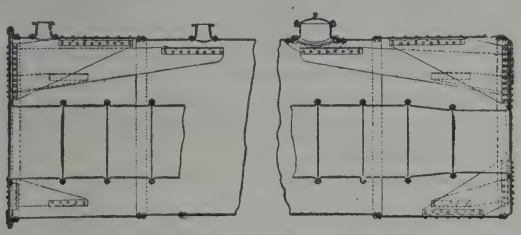

FIG. 9.—Lancashire Boiler (ordinary type, with flat end plates).

When steel took the place of iron, and boiler makers were able to obtain larger plates, the end plates of the largest boilers were then made in one piece, and the shells constructed of seven or nine belts, each in one plate. Fig. 9 shows a section of one of these Lancashire boilers as it is still being made by some firms.

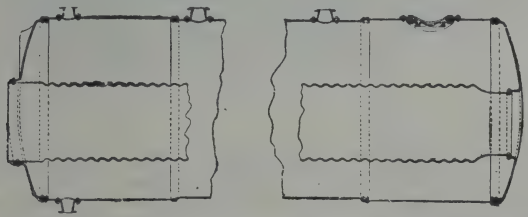

FIG. 10.—John Thompson Type, with dish end plates and corrugated flue tubes.

All internally-fired boilers are subjected to straining due to unequal expansion and contraction, the flue tubes and furnace tubes becoming hotter than the shell while the boiler is at work.

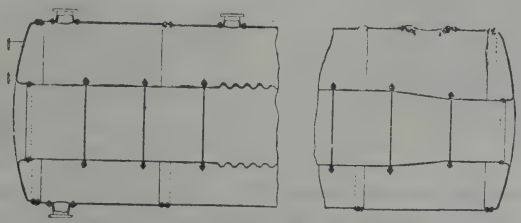

FIG. 11.—John Thompson Type, with flue tubes corrugated for part of their length.

Makers of boilers having flat end plates provide for expansion by the flexibility of the end plates.

Some makers avoid the staying required in the case of flat end plates by using dish-end

plates (fig. 10), and provide for the relief of expansion stresses by making the flue tubes corrugated, either for their whole length (fig. 10), or for part of their length (fig. 11).

A length of corrugated flue tube is used by makers of flat end boilers also, for high pressures.

THE GALLOWAY BOILER.

The general design and details of the Galloway Boiler (*Galloways, Ltd., Manchester*) are shown by fig. 12. The boiler has two furnaces at the front, joining behind the bridges into one flue of special shape, containing the well-known Galloway cone tubes, and side pockets; otherwise, and in general appearance, it is somewhat similar to the two-flued or Lancashire boiler.

The advantages claimed for the Galloway boiler are:—

Increased heating surface—about 10 per cent. additional.

Improved circulation, giving more uniform temperature and reduced expansion strains. This circulation, also, largely prevents the deposit of solid matter upon the furnaces and adds to the durability of the boiler.

Improved heat transmission, owing to good circulation and to sinuous path of flue gases past the cone tubes.

Increased output and higher efficiency.

THE JOHN THOMPSON LANCASHIRE BOILER.

(*John Thompson (Wolverhampton), Ltd., Wolverhampton.*)

This is a boiler (fig. 13, p. 1640) of the dish-end type (figs. 10, 11). The end plates are dished to a convex form and increased in thickness to give the same factor of safety (as obtained with the stayed surface), thereby dispensing with all gusset and longitudinal rod stays. The inside, being free from stays, can be easily cleaned, particularly over the fire-boxes, where the steam is so largely generated.

The table on page 1639 gives some particulars of these boilers, which have been made for working pressures up to 230 lbs. per sq. in.

MULTITUBULAR BOILERS, LOCOMOTIVE TYPE.

THE ROBEY BOILER.

Fig. 14 shows a boiler, locomotive type, by Messrs. Robey & Co. Ltd. of Lincoln. It is rated at 8 h.p. nominal, with enlarged grate suitable for burning inferior fuel, having a grate area of 6·43 sq. ft., and a total heating surface of 164·8 sq. ft. Its working pressure is 150 lbs per sq. in. The tubes are of steel solid drawn.

The figure shows Messrs. Robey & Co.'s patent roof fire-box girders, which, being supported by the archplate of external fire-box, take all compressive strains off the fire-box front plate and tube plate.

DIMENSIONS OF 8 H.P. LOCOMOTIVE BOILER.

FIG. 15.

Paxman Boilers.

(Davey, Paxman & Co., Ltd., Colchester.)

The Paxman Vertical Multitubular Boiler.

(Prov. Prot.)

This type of boiler has been designed to supply the demand for a boiler which occupies a minimum of space, does not require any brickwork setting, and at the same time does not sacrifice its economy in achieving these objects. Owing to the design a greater heating surface and consequent evaporation can be obtained than with any other design of vertical boiler of the same diameter, without in any way interfering with the accessibility for inspection and cleaning. The special features of the design, which have made it possible to achieve these results, are as follows:—

The general construction of the boiler is shown by sectional views figs. 16 and 17. A straight neck C, secured to the top of the firebox B, conveys the products of combustion into a chamber to the left G, from whence they pass through the horizontal smoke tubes A, to a similar chamber on the other side H, provided with door and uptake, constituting a smokebox. The first chamber or combustion chamber G is lined with firebrick, which, retaining the heat, ensures complete combustion of the gases before they enter the tubes. This chamber is also provided with a door, so that the tubes are easily accessible for cleaning purposes.

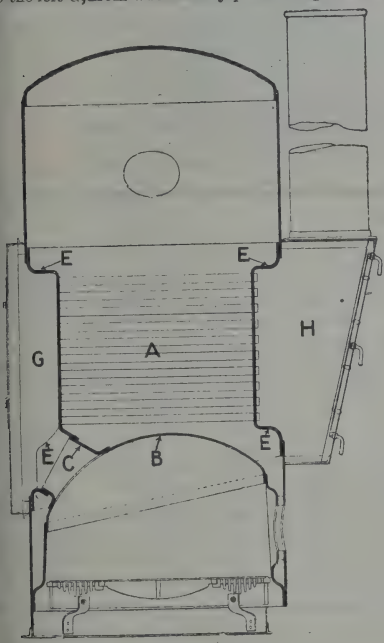

Fig. 16.

The construction of the firebox forms one of the special features of the design, the inclination of the joint of the crown B enabling the neck C to be so placed as to allow of more tubes being inserted without increasing the height of the boiler.

Another very important feature is the design of the pockets forming the tube plates. Unlike the usual practice using deep independent pockets riveted to the shell, these are pressed out of the solid shell plate, thus allowing them to be of a

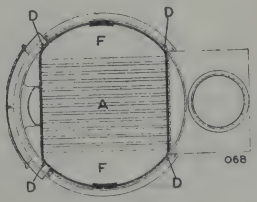

Fig. 17.

minimum depth and dispensing with any riveted joints beyond those in the shell plates themselves.

The advantages of this form of construction are considerable: the absence of loose riveted pockets increases the strength of the boiler shell, does away with all chances of trouble with leaky seams and rivets, and at the same time the reduction in the depth of the pockets allows of a considerable increase in the length of the tubes, and consequently in the heating surface, without increase in the diameter of the boiler, thus improving the proportion of heating surface to grate area, with the result that the efficiency is sensibly increased.

The reduction in the depth of the pockets has the additional advantage of doing away with the necessity of staying the tops or bottoms of these pockets.

The additional heating surface obtained by increasing the length and number of the tubes in no way affects the accessibility of the boiler for cleaning purposes. As will be seen in fig. 17, the spaces F, through which access to the tubes and crown of firebox is obtained, will remain unaltered by the length or depth of the complete nest of tubes.

The advantages of this boiler can be briefly summarised as follows:—

1. Ease of erection owing to absence of brickwork setting or special foundations.
2. Increased evaporation per square foot of floor space occupied.
3. Greater economy owing to better proportion between heating surface and grate area.
4. Ample accessibility for cleaning and inspection of all internal parts.
5. Elimination of riveted joints round pockets.
6. No staying required in any part of the boiler.

The boiler can be supplied for evaporation up to 6,000 lbs. per hour, and for working pressure between 80 and 160 lbs. per square inch

THE PAXMAN ECONOMIC BOILER.

This boiler (fig. 18) consists of a cylindrical shell, with one or more internal flues, and a number of small return tubes running from end to end. A combustion chamber of brick receives the products of combustion at the back of the boiler; they then pass through the small tubes to the smokebox in front, and finally return to the back, outside the boiler shell, through the brick flues in the setting, to the chimney.

Whilst the temperature of the waste gases which leave the boiler on their way to the chimney ranges from 600° to 700°F. with many boilers of the Cornish, Lancashire, or similar types, it is

only from 450° to 475°F. in the case of the Paxman 'Economic'; with the latter boiler, on account of its large heating surface, there is about 30 per cent. less waste of heat, the temperature named being just sufficient to create a natural draught, indicating that the utmost possible degree of heat has been abstracted from the fuel burnt, and rendering an Economiser unnecessary.

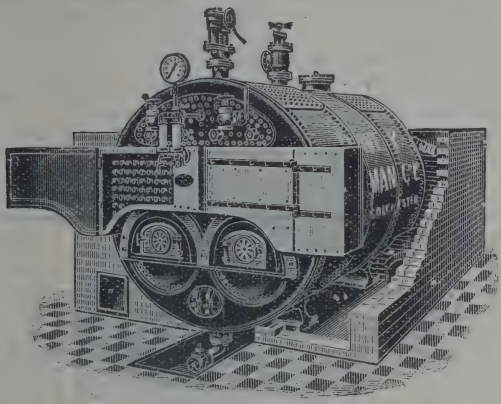

FIG. 18.

An independent test of this boiler by Sir Alexander W. B. Kennedy showed an evaporation of 12·2 lbs. of water from and at 212°F. per lb. of coal.

The operation of sweeping the tubes (preferably daily) can be effected by the stoker, using an ordinary wire tube brush, during any interval of thirty minutes; or, if there is no such interval, a steam cleaning device can be supplied, enabling the operation to be completed in two minutes.

A Paxman 'Economic' boiler being only about half the length of a Lancashire boiler of corresponding capacity, a very considerable saving is effected in the boiler setting and buildings; and in case of shipment the freightage cost may be only one-third of that for a Lancashire boiler.

* The figures given for the evaporative capacity of each boiler are with feed at 212°F., when burning good coal, and with good draught and stoking. It is of course possible to obtain a much greater evaporation when the draught is ample, and the user is prepared to sacrifice economy to increase the evaporation.

The Cochran Boiler.

(Cochran & Co., Annan, Ltd., Annan, Scotland.)

The boilers (fig. 19, p. 1647) are used very largely both ashore and afloat; the advantage which they present over other kinds for land use and export consists, principally, in great economy of space, in not requiring any brickwork setting, in having a large amount of highly effective heating surface, in obtaining plenty of steam, and in being very economical in fuel, besides being perfectly accessible for cleaning and repairs outside and inside.

For winch boilers this type combines the advantage of the cross-tube boiler and the horizontal boiler without their disadvantage, and has been found the most suitable for large passenger, mail, and cargo steamers running to all parts of the world.

The boilers are made in a range of standard sizes, as per following Table, which gives full particulars of their standard dimensions.

Evaporation of Cochran Boilers.

Messrs. Cochran's formula for evaporation is :—

$$E = 26\,(G - 2)\left(5 + \frac{\frac{H}{G} - 13}{7{\cdot}5}\right)$$

where,

E = Evaporation in lbs. per hour; G = Grate area in sq. ft.; H = Heating surface in sq. ft. The first expression of the formula represents the coal burnt per hour; the second expression represents the water evaporated per lb. of coal.

PROGRESS

Stirling Boilers are operating at working pressures up to 1400 lbs. per square inch, and can be supplied for evaporations up to 500,000 lbs. of water per hour.

THE STIRLING BOILER COMPANY, LIMITED

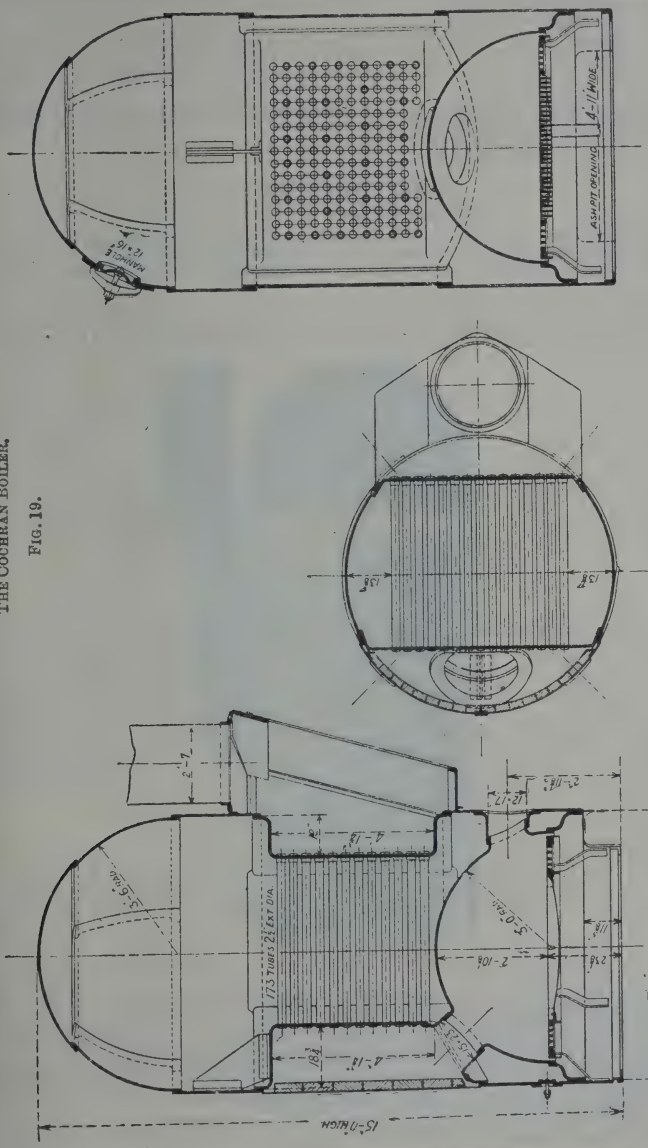
STIRLING BOILERS

F. 1647



THE COCHRAN BOILER.

FIG. 19.

The evaporations given by this formula can be obtained under favourable conditions, but the makers' practice is to recommend that about 75 per cent. of this maximum evaporation should be relied upon for continuous working.

In the Evaporation table (p. 1646) it will be noticed that there are two sets of figures, showing coal consumption and evaporation. Under 'Heavy Steaming' are given the evaporations as per formula, and under 'Easy Steaming' the evaporations are calculated at 75 per cent. of this amount.

An adaptation of the standard Cochran boiler recently introduced to meet the requirements of hot-water service and heating schemes has met with a considerable measure of success. For particulars of this boiler, see p. 2498.

The Beardmore-Blake Boiler.

(William Beardmore & Co., Ltd., Glasgow.)

This boiler, fig. 20, is specially adaptable for use as an auxiliary boiler for steamers, coal or oil fired, steam cranes, and for utilising the waste heat from furnaces, etc.

The boiler is simply installed, occupies very little ground space, no brick settings being required.

Special features are the following:—

There are no flat surfaces; the circularity of the shell and combustion chamber is not broken into by the introduction of flat tube plates, consequently neither stays or stay tubes are required.

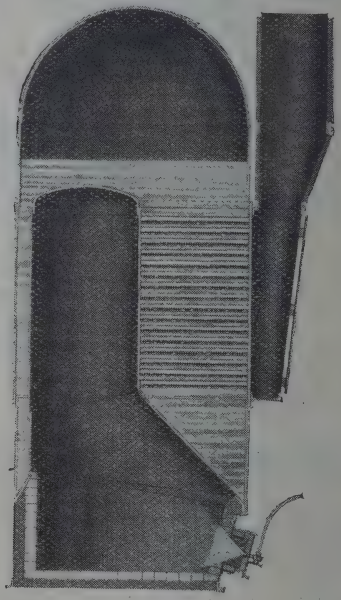


Fig. 20.

A large 'wet back' circular combustion chamber is provided having from 25 to 80 sq. ft. of heating surface, according to size of boiler, every square foot of same being equivalent to 3 sq. ft. of tube surface, thereby greatly increasing the evaporative power and efficiency of the boiler.

The tube plates are truly circular, the tube holes being drilled to provide a true bearing and ensuring a perfectly tight joint by rolling with an ordinary tube expander.

There is no undue stress on the ends of the tubes as in boilers with flat tube plates (which the tubes have to support), a number being screwed into the flat tube plates to act as stays.

Accessibility to all parts for cleaning and examination.

The wide spaces between the tubes facilitates the passage of steam, promoting rapid circulation with maximum generation of steam.

The heating surface is so effective that the maximum heat is absorbed in the generation of steam, the temperature of the gases leaving the tubes being only what is necessary to provide the requisite draught for combustion.

The large cubical capacity of the firebox and combustion chamber, which is so essential for oil fuel to obtain the highest efficiency and maximum evaporation, is provided in this type of boiler.

For utilising waste heat, provision can be made on the boiler for auxiliary hand firing, and this is generally desirable in connection with forge furnaces which may be intermittent in working, or, if at any time a furnace is out of operation, complete coal firing may be resorted to.

WATER-TUBE BOILERS FOR LAND SERVICE.*

THE NICLAUSSE BOILER.

This boiler consists of a compact nest of large, straight, short solid drawn tubes, closed at each end and mounted at the front end in solid drawn pressed steel headers, upon the top of which is mounted a capacious steam and water drum. There is thus only a single row of headers. The heating surface of the outer tube is rendered highly efficient by the provision of an inner tube to carry the water to its back end, whereby the circulation must always be in only one, and that the correct, direction. The tubes are closed by a tapered screwed pressed steel cap at the back end, and at the front end by a tapered screwed pressed steel plug, to which is attached the inner tube by a swivelling connection, whereby it can be readily withdrawn. Both plugs and caps can be easily removed for inspection and cleaning. It is generally sufficient to remove the front plug and withdraw the inner tube once a year for washing out by means of a hose applied to the outer end of the inner tube *in situ*.

THE VICKERS WATER TUBE BOILERS.

(Vickers Boiler Co., Ltd.)

These boilers (figs. 21 and 22) comprise the 'Bent' Spearing 'Header' type and Tube type.

The Vickers 'Bent Tube' type boilers comprise both three-drum and five-drum patterns.

The Spearing 'Header' type boiler may comprise three drums, viz. the main drum at the rear with mud drum and circulating drum at the front, or alternatively two drums only, viz. main steam and water drum and mud drum. Boilers of this type may be arranged either with the two drums at the front or the rear. A further design of the header type boiler is a patent double-circulation boiler which is specially designed for giving a very high rate of evaporation per sq. ft. of heating surface.

All 'Header' type boilers embody the special features associated with the Spearing type of boiler, viz. a mud drum usually of 2 ft. 6 in. internal diameter, downcomer pipes of large area connecting the main steam and water drum with the mud drum, straight solid drawn weldless steel headers of large area with staggered tubes, and also connecting nipples of large area.

These special points in design have been embodied with a view to ensuring positive circulation under all operating conditions, and also to ensure the precipitation of all solids in the mud drum for blowing off. In practice it has been found that the downcomers are of the utmost practical

* See Section XXXVI, p. 2388, for Marine Service.

THE VICKERS BOILER.

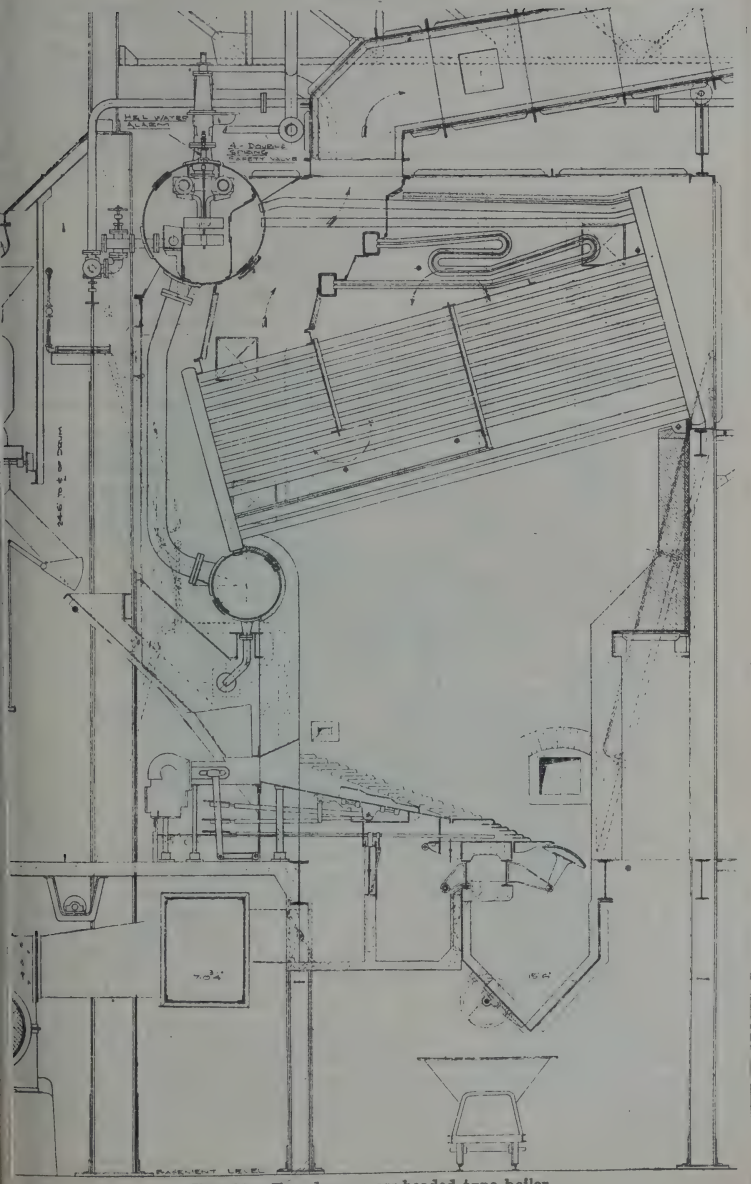

FIG. 22.—Two-drum cross-headed type boiler.

value from the point of view of effective circulation, and in ensuring an uninterrupted supply of feed water in a proper cycle from the main steam and water drum through the mud drum to the bottom rows of tubes first. This positive circulation also makes this type of boiler an extremely efficient and satisfactory steam generator under overload conditions.

The value of the large mud drum in conjunction with the downcomer circulating system, and the precipitation of suspended solids in the water in the mud drum has enabled this boiler to be efficiently used with extremely unsatisfactory feed water without any detrimental effect upon the boiler tubes, and it is very rarely indeed that any deposit whatever is found in these tubes.

Figs. 21 and 22 show: (1) The Vickers three-drum cross-header type boiler; (2) the Vickers two-drum cross-header type boiler.

Boiler units of the header type have been made up to an evaporative capacity of 100,000 lbs. per hour, and of the bent-tube type up to an evaporative capacity of 60,000 lbs. per hour.

The Clarke-Chapman Water-Tube Boiler.

(Woodeson's Patent.)

(Clarke, Chapman & Co., Ltd., Gateshead-on-Tyne.)

The 'Woodeson' Patent Water-tube Boiler, as shown by figs. 24–26, consists of three sections, each comprising steam drum, water drum, and a number of groups of tubes expanded into same; these tubes are nearly vertical and perfectly straight, and manholes are arranged on steel drums immediately over each group through which any tube can be withdrawn.

A spacious steam dome is arranged over the steam drums to ensure a supply of dry steam and to maintain a steady water level. The bottom drums are absolutely hanging so that expansion and contraction can take place without effecting any damage to boiler.

The boiler as shown is also fitted with a Clarke-Chapman Patent Superheater between the front and centre sections.

In the design of the 'Woodeson' boiler, a special feature is the ease of access for purposes of examination or repairs, the time which has to be expended on same being practically reduced to a minimum; thus in a boiler of, say, 6,100 square feet of heating surface, containing 456 tubes, the

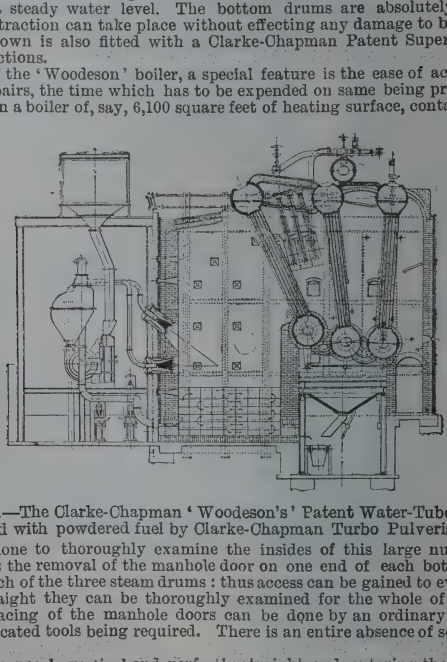

Fig. 23.—The Clarke-Chapman 'Woodeson's' Patent Water-Tube Boiler fired with powdered fuel by Clarke-Chapman Turbo Pulveriser.

only work to be done to thoroughly examine the insides of this large number of tubes for their total length is the removal of the manhole door on one end of each bottom drum and one manhole door off each of the three steam drums: thus access can be gained to every tube, and these being perfectly straight they can be thoroughly examined for the whole of their length. The removing and replacing of the manhole doors can be done by an ordinary fireman, no skilled mechanic or complicated tools being required. There is an entire absence of screwed joints in the boiler.

Each tube being nearly vertical and perfectly straight and entering the steam drum direct without intervention of any headers, ensures a perfect steam release, and so adds to the efficiency of the boiler, as there are no sharp turns to retard flow of the steam globules to the steam space. Also, deposits are not retained in the tubes, but are collected in the large mud-drums: thus over-heating and destruction of tubes are reduced to a minimum. The Woodeson Patent Water-Tube Boiler is also eminently suitable for firing with Powdered Fuel as shown in fig. 23.

FIGS. 24–26

THE STIRLING WATER-TUBE BOILER.

(*The Stirling Boiler Company, Ltd.*, 32–33, *Farringdon Street, London, E.C.* 4.)

This boiler consists of two or more upper drums, containing water and steam, connected by banks of tubes to one or more lower water drums, the upper drums being further connected by several rows of steam and water circulating tubes.

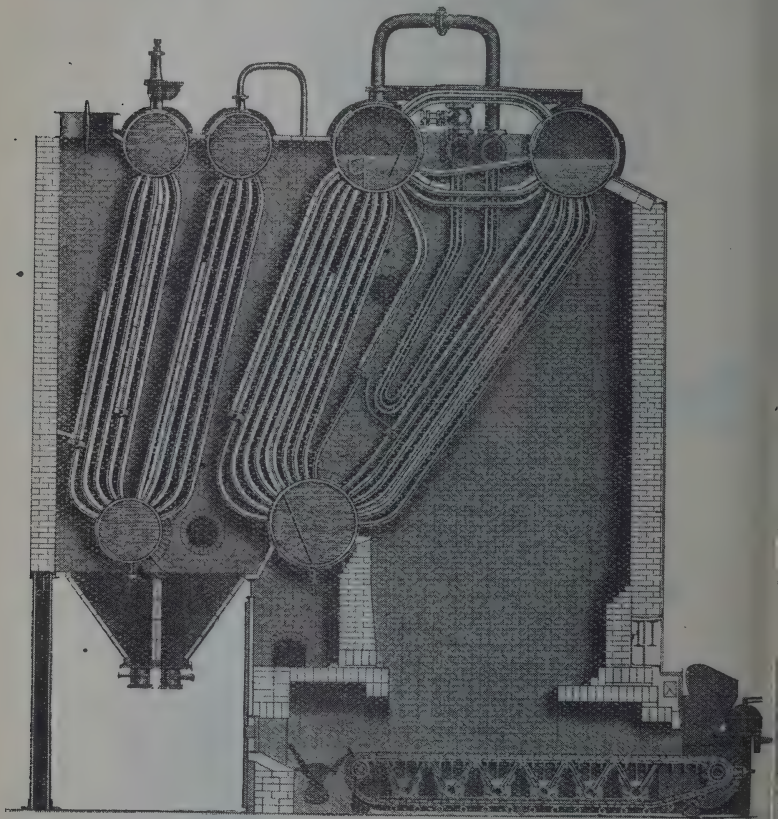

FIG. 27.—The Stirling Boiler.

The type of Stirling boiler shown in fig. 27 is termed the 'Tri-drum' boiler. It is the latest type of this generator, and is essentially a high duty boiler, with a rapid circulation, quick steam generation and a large evaporative capacity, the products of combustion being brought directly into intimate contact with the outer surfaces of the tubes, and directed by a system of baffles to secure the maximum heat interchange between these gases and the water.

The tubes are of solid drawn steel, and are 3¼ in. external diameter. As will be seen from the figure, the Stirling tubes are curved at the ends, permitting them to enter the drums radially, thereby allowing not only for a maximum number of tubes to be connected to the drum, but also for a natural expansion and contraction in each individual tube, thus ensuring tightness and at the same time flexibility.

The tubes are expanded into the tube plates, the projecting tube ends within the drums being either belled or beaded over; thus each tube has a discharge outlet of its full area for the escape of the steam as generated, so obviating steam pocketing in the tubes, with its attendant risks of blistering, etc. The Stirling boiler tubes are slightly inclined to the vertical to enable the front bank tubes to absorb much radiant heat and to receive from the gases the maximum heat by convection.

The drums are made of best quality open-hearth steel and undergo hydraulic test pressures before leaving the makers' works.

All portions of the boiler are circular in form, eliminating any tendency to deformation of any part owing to internal pressure, and certain types of this boiler are already operated at a working pressure of 1,400 lbs. per square inch.

The boiler is entirely independent of the brickwork, the upper steam and water drums being either carried on a steel framework or suspended by slings from overhead beams, while the lower drums are supported by the tubes from the upper drums, leaving the whole boiler freedom of movement with changes of temperature.

The water circulation, practically throughout the whole course of its progress through the boiler, is travelling in a direction opposite to that taken by the gases, thus securing throughout the whole surface of the boiler a very high efficient heat transmission rate. The feed water is introduced into the rear drum and becomes highly heated before reaching the front bank, scale forming matter, if present, being thrown down in the rearmost banks of tubes and preserving cleanliness in the main front bank generators.

By means of patent diaphragms in the rear drums, incoming feed water has to traverse two passes in the rear bank of tubes before joining the main body of water already in circulation, giving a gradual rise in the temperature of the water throughout the boiler, with the corresponding gradual approach to the greatest temperature of the gases, *i.e.* the combustion chamber.

A patent separating baffle is also fitted into the upper rear drum to intercept the mixture of steam and water issuing from the ends of the water cross tubes. This mixture is separated into its components within the confined space of the baffle, the water flowing quietly into the water space of the drum, while the steam is discharged above the water level. By directing the steam port downwards there is a tendency to throw down into the water space the last trace of residual moisture left in the steam. The presence of this baffle produces a state of quiescence in the drum a necessary condition for dry steam), an unusual high dryness factor for the steam (essential for a high degree of superheat), and the cleanliness of the superheater, valves and entire steam circuit.

The overall sizes of the Stirling boiler of a given heating surface can be arranged to suit varying conditions, the design of boiler being adaptable equally well for boiler houses with low roof and ample width as for those having little width and ample height.

A marine type of this boiler is also supplied, which may be used for landwork when the space available is very limited.

Stirling boilers are designed for all evaporations between 4,000 lbs. and 500,000 lbs. of water per hour, and working pressures between 100 lbs. and 1,400 lbs. per square inch.

The boiler is easily cleaned, this being effected on the tubes on the external sides by a system of steam soot blowers, or by hand-operated steam lances; the internal sides (access to which is made by the simple operation of removing three manhole doors) are cleaned by means of water-driven turbine cleaners. This water, supplied through a flexible hose, rotates small cutters, varying in form according to the nature of the scale to be removed. The exhaust water from the turbine washes the refuse into the lower water drum, from which it is easily drained off through the blow down pipes.

All other parts of the boiler are easily accessible by the conveniently placed access and sooting doors. The rare occurrence of a renewal of Stirling tubes is provided for by any tube being able to be removed without sacrificing the neighbouring good tubes.

Taking a great number of tests extending over a period of many years, the efficiency of the Stirling boiler averages from 80 to 85 per cent.

This boiler will give the highest satisfactory results with all classes of fuel and methods of firing, whether pulverised fuel, mechanical stokers, or oil burners, while it is largely in use for the utilisation of waste heat, whether in the form of blast-furnace gas, waste heat from coke ovens, or heating and puddling furnaces. It is a boiler much used in power stations, paper works, gas works, etc.; it is also largely employed on sugar estates abroad, fired with bagasse in special furnaces.

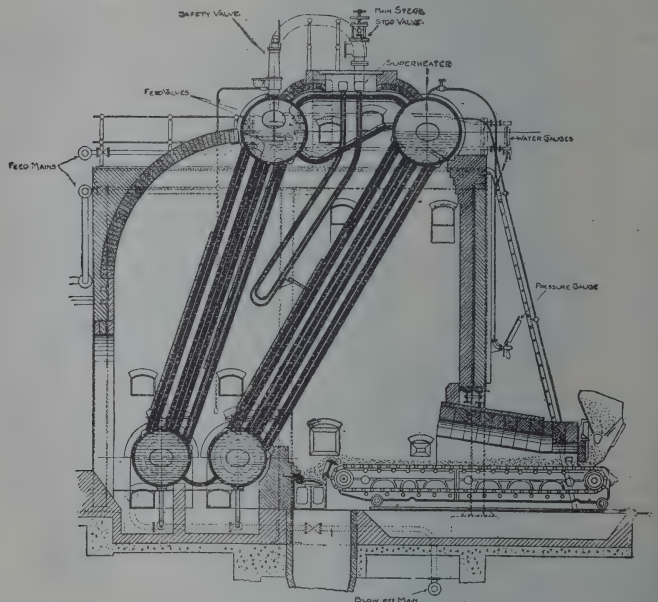
The Galloway Five-Drum Water-Tube Boiler.

This is generally similar to the 'Stirling' type boiler, and has been designed for large units and high efficiencies. The arrangement is easy to keep clean internally.

The 'John Thompson' Patent Straight Tube Water-Tube Boiler.

(John Thompson Water Tube Boilers Ltd., Ettingshall, Wolverhampton.)

This boiler (fig. 28) consists of either two, four, or six drums, one, two, or three at the top for steam and water, and a corresponding number at the bottom. Each series of drums is brought into communication one with the other by a number of short circulating tubes, whilst large straight tubes, set nearly vertically, connect the top drums with those at the bottom. By this means the water, which is fed into the boiler from the back of the steam and water drums, passes down the back row of tubes, each of which has a discharge outlet equal to its full area, and thus affords a free, rapid, and continuous circulation which in its turn prevents the deposit of scale on the heating surface of the tubes.



Patent

Fig. 28.

The six-drum type of boiler is known as the Integral Economiser Boiler, the back or third bank of tubes being the Economiser.

The drums shown in fig. 29 are of mild steel and longitudinally divided into halves, the portion which receives the tubes being hydraulically formed into a series of impressions, enabling the tubes to enter the tube plate at right angles.

The following points are special features:

1. *Tubes.*—The tubes are so arranged, as to spacing, that any one tube may be removed and replaced without in any way disturbing any others.

The tubes are all passed in and out of the boiler by way of the fire-door opening, thus saving the necessity for extra head room.

Each tube can be examined throughout its whole length by holding a lamp at one end.

Telephone: REGENT 3216 (2 lines). Telegrams: "WATERTUBE, ESTRAND, LONDON."

F. 1657

2. *Drums.*—The steam and water drums are of a large and ample capacity, so essential for the obtaining of dry steam, and thus giving large thermal storage.

Any scale that may be deposited in the boiler falls into the mud-drums at the bottom.

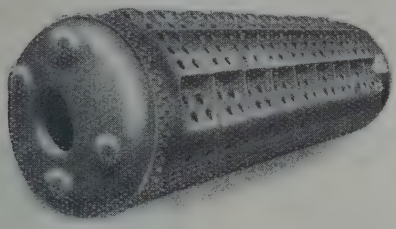

FIG. 29.

3. *Boiler.*—The boiler is suspended from steel girders which rest on steel columns based in cast iron; it is thus entirely independent of the brickwork, ensuring freedom for expansion in every part, and enabling the brickwork to be removed and replaced, if necessary, without in any way disturbing the boiler or its connections.

The largest size of these boilers can be cleaned and restarted in full work within the period of three days, there being only one manhole joint in each drum to be made.

The Babcock & Wilcox Patent Water-Tube Boiler.

STANDARD LAND TYPE.

The structure of this boiler (figs. 30, 31), composed entirely of wrought steel, may be practically considered as having three distinct parts, namely:

A series of inclined water tubes placed over the furnace, in which the water, being divided into small volumes, is quickly raised to a high temperature and rises, at the front end, through vertical connecting boxes or headers (into which the tubes are expanded).

A horizontal steam and water drum, up to which the water rises from the headers, and where the steam separates from the water, the remaining body of water returning through the vertical tubes and headers at the back end into the inclined water-tubes, where it is again subjected to the action of the fire, and again passes into the steam and water drum; thus, a continuous and rapid circulation is kept up, and a uniform temperature maintained throughout the boiler.

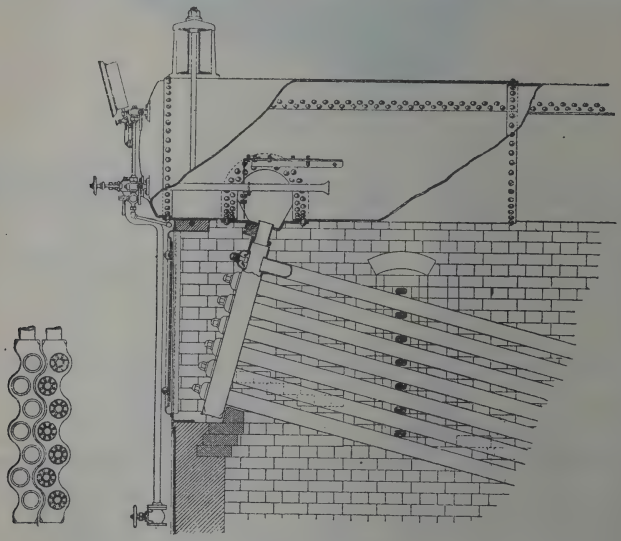

FIG. 30.—Vertical Section showing details.

A *mud-collector* is attached to the lowest point of the inclined water-tubes, into which the matter held in suspension in the water is, to a large extent, precipitated by its specific gravity.

The inclined water-tubes are of steel and the headers at each end into which they are expanded are sinuous (or staggered) and of mild steel, each complete section consisting of one zigzag row of tubes, expanded into a rear and front header. The headers are provided with handholes placed opposite the ends of each tube to permit of cleaning, and, in case of need, the removal of a tube, each handhole being provided with a cap fastened with a wrought steel bolt and clamp and a cap nut, the handhole covers being placed metal to metal. The top ends of each section are connected to the steam and water drum, not directly, but are first expanded into specially designed cross-boxes, which are riveted to and extend from the underside of the drum at each end. The steam and water drum is made of the best selected mild steel double riveted for ordinary purposes; the mud drum is made of mild steel, and is provided with ample facilities for cleaning.

The entire boiler, except the furnace, is suspended by wrought iron slings, from iron girders resting on wrought iron columns, to allow the boiler to expand or contract without straining the brickwork. The boiler and furnace are enclosed in masonry lined with firebrick, the furnace being arranged below the tubes, and firebrick baffles compel the hot gases to pass upwards, then downwards, then upwards again before escaping to the chimney. These hot gases strike the tubes at right angles, thus intercepting the radiant heat from the fuel as effectively as possible; the tubes being zigzagged, the gases are thoroughly broken up as they rise, and, passing into the

WATER-TUBE
STEAM BOILERS
FOR ECONOMY

The Babcock & Wilcox Water-tube Boiler gives a maximum evaporation per square foot of floor space. At the Barton Power House, belonging to the Manchester Corporation, which is exclusively equipped with B. & W. Boilers, the coal consumption is only 1.36 lbs. per unit generated.

AND EFFICIENCY

An analysis of the last published returns issued by the Electricity Commissioners for the year ending March 31st, 1926, shows that all the Power Houses with the highest overall Thermal efficiency, i.e. from 21.5% to 17%, are equipped with Babcock & Wilcox Boilers.

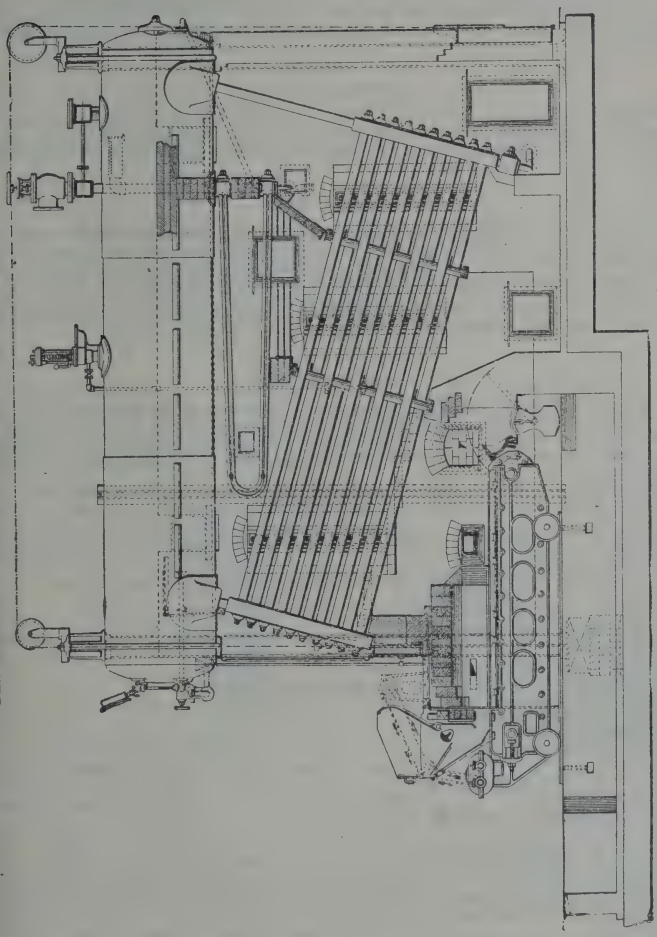
THE BABCOCK & WILCOX PATENT WATER-TUBE BOILER.



(FIG. 31.—Boiler fitted with Superheater and Stoker.

combustion chamber under the drum, they expand and combine before again passing the secon and third time through the tubes and on to the flue; thus complete combustion, rapid steamin and consequent economy are secured.

The damper for regulating the draught and flow of the gases is placed in the back chambe whilst doors for cleaning the tubes and removing soot are placed on one side of the brickwork.

A comparison of space is afforded by a works, where six Lancashire boilers, evaporatin 48,000 lbs. of water per hour, are placed beside four Babcock & Wilcox boilers of the abov type, evaporating 40,000 lbs. of water per hour under the same conditions. The ground spac occupied by each range of boilers is in the ratio of 10 for Lancashires to 4½ for Babcock Wilcox boilers.

CROSS-TYPE BOILER.

The general construction of this form of boiler is the same, but the drum is placed transversel instead of longitudinally, with the tubes, and the whole boiler is constructed in pieces of compara tively light weight suitable for transport in countries where ordinary means of carriage are no available.

PORTABLE BOILER.

This form is similar to the last described, but is still further sectionalised in the drum portion which is arranged to be riveted up on site. The boiler is also provided with an iron casing line with firebrick, and is thus self-contained and independent of the brickwork. This type is also used for countries where transport and facilities in the matter of construction are not available.

In addition to the above types, the boilers are arranged with special furnaces for burning saw dust, lignite, rice husks, bagasse, coke breeze, refuse, coal, gas, and oil fuels.

MARINE TYPE BOILER.

In general construction this boiler (see page 2389) is similar to the foregoing, but with the steam and water drum placed transversely and brought to the front. The principal difference between this boiler and those already described is the largely increased grate area, enabling the boiler to give a greatly increased evaporation per square foot of heating surface compared with the other types.

The 'O T' marine type of boiler, of large evaporative capacity, is fitted with a superheater chain-grate stoker, and superposed economiser, for evaporating up to 250,000 lbs. of water per hour.

Batteries of these boilers are now installed working at pressures up to 1,200 lbs. per square inch.

THE HOWDEN H.P. BOILER.

(*James Howden & Co., Ltd.*, 195 *Scotland St., Glasgow.*)

A few of the leading features of this boiler (fig. 32) are as follows :—

1. Reduced weight of boiler and of the water in comparison with Marine Cylindrical Boiler of similar output, approximately 40 per cent.

2. Reduced diameter of shell and thickness of plate.

3. Simplicity of construction.

4. No flat combustion chamber surfaces requiring staying.

5. Shipment of boiler could be made in sections, involving lighter weights to be handled, and also reduction in the spaces left open for the shipping of boilers.

6. In this design the most valuable features of the ordinary cylindrical boiler have been retained.

7. There is ample steam space and steam liberating surface, which will avoid any tendency to priming.

8. A minimum amount of brickwork, and as brickwork and casings are not exposed to high furnace temperatures, the losses by radiation are reduced and the temperature of the stokehold would not be any higher than in the case of a cylindrical boiler.

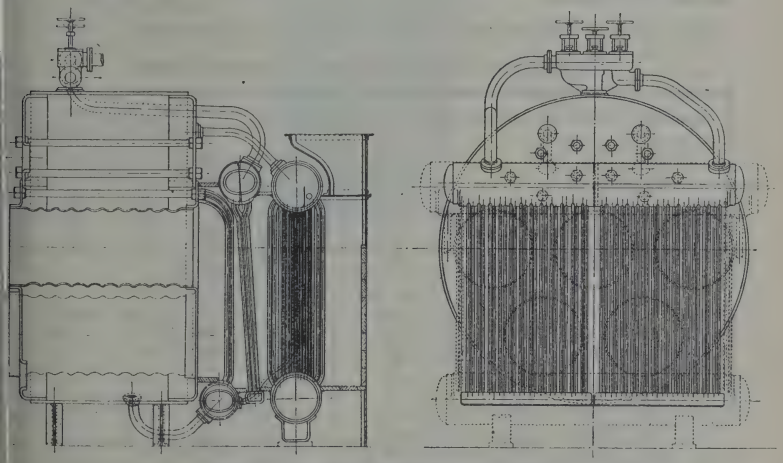

FIG. 32.—Typical Howden H.P. Boiler.

9. The water tubes are subjected only to the comparatively low temperature of the combustion chamber gases, without radiation effect from the fuel. They are, therefore, from the point of view of temperature, in the same condition as the middle and back row tubes of a water tube boiler, so that trouble by overheating should not occur and the life of the tube should be correspondingly prolonged.

10. Any mud introduced with feed water or scale would be deposited in the lower water tube drum, which is not subjected to flame, and where it could be readily removed.

11. The boiler is readily accessible for cleaning and inspection, both in combustion chamber and internally.

The 'Spencer-Hopwood' Patent Boiler.

This, a vertical boiler with inclined water-tubes (manufactured by *Messrs. Spencer-Hopwood Ltd., Hitchin, Herts*), has the tubes spread immediately over the fire, making it extremely rapid in steam raising); 100 lbs. pressure per sq. in. can be obtained from cold water in the boiler in thirty-five minutes from the time of lighting the fire. A number of mandoors of the McNeil type are provided opposite both ends of the nest of tubes, giving easy access to them and also to the entire interior of the boiler for cleaning and renewal purposes.

The standard 'Spencer-Hopwood' patent boiler will evaporate from 25 to 50 per cent. more steam than a vertical cross-tube boiler of the same dimensions.

This boiler is also made in a squat pattern for use where head room is limited, and most modern railway breakdown cranes are fitted with it.

Recently a new and improved 'Spencer-Hopwood' patent boiler has been put on the market for standard pattern sizes Nos. 16 to 24. These have a much deeper nest of tubes than before resulting in a higher thermal efficiency and still smaller space required for the output. In the smaller sizes this is done by arranging the major axes of the manholes in a vertical direction instead of the usual horizontal one, and using more than two, thus deepening the nest of water-tubes 33 per cent. In the larger sizes there are two or three rows of manholes, which enables the nest to be deepened as much as 100 per cent. Further, by the use of more than two manholes per row of manholes, the width of the tube nest can be increased to anything desired, enabling these boilers to be made up to 6 ft. diameter and over, to evaporate up to 5,000 lbs. of steam from and at 212° F. per hour, so that they can be installed to do the work of a small Lancashire boiler and to give as high an efficiency, without the floor space, without the brick setting, without the chimney, and without the necessity of taking hours to raise steam.

Where superheated steam is required, a superheater can be supplied for all sizes, which is arranged in the uptake.

Stock boilers are built for working pressures up to 120 lbs. per square inch.

The evaporations given are based on actual tests with 5 ft. of chimney only, feed water at 60° F., steam at 100 lbs. pressure per sq. in., and good steam coal.

Induced draught is obtained from a steam jet included with the boiler mountings.

These boilers fired with oil evaporate 25 per cent. to 30 per cent. more than the (natural draught) figures given above for coal.

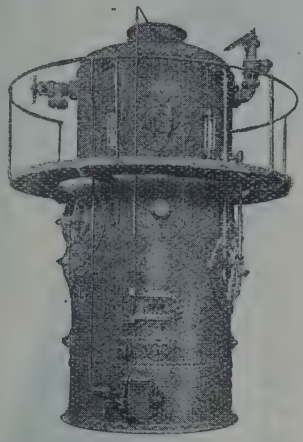
SPECIFY
SPENCER-HOPWOOD PATENT WATER-TUBE VERTICAL BOILERS

IF you are intent on obtaining the maximum results from a Donkey Boiler which costs the least to run and the least to maintain, read the following eleven points about the Spencer-Hopwood Vertical Boiler:

I.
Costs no more than other boilers of the same output.

II.
Raises steam from cold in HALF-AN-HOUR day after day without any injurious effects.

III.
Occupies less floor space than any other boiler for the same output.



IV.
Has no rivet heads subject to high flame temperatures.

V.
Is the most accessible for cleaning and inspection.

VI.
The tubes are immediately accessible for renewal, inspection, or internal cleaning, by removing the easily-handled mandoors at the side.

VII.
The tubes can be cleaned on the fire side with a lance while the boiler is working.

VIII.
33% Overload Capacity.

IX.
Lowest Maintenance Costs.

X.
Highest Evaporation for size.

XI.
Greatest Heating Surface for size.

SPENCER-HOPWOOD PATENT WATER-TUBE VERTICAL BOILERS ARE USED ALL OVER THE WORLD.

The 'Sulzer' Water-tube Boiler.

This boiler (*Sulzer Bros., London*), shown in fig. 33. is constructed in the single and double bank type. Its main features are:—

Perfectly straight and nearly vertical tubes, preventing 'hogging,' and minimising the amount of deposit on same, resulting in the intimate contact of the tubes with the products of combustion, therefore larger heating surface than would be obtainable with slanting water-tubes.

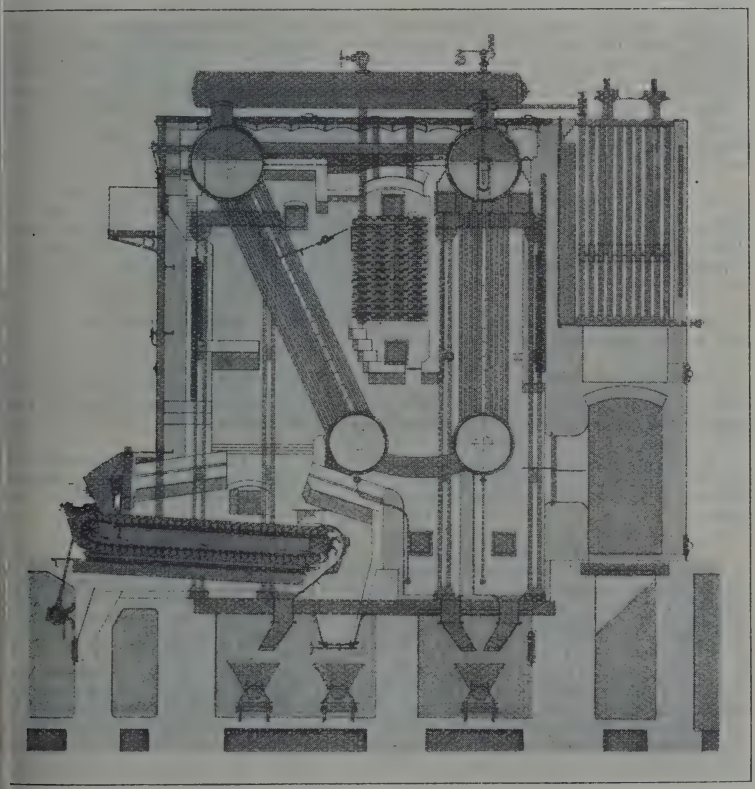

Fig. 33.—Sulzer Double-bank Four-pass Vertical Water-tube Boiler.

The tube-plates are shaped so as to reduce the strain on the material to a minimum.

Free suspension of the boiler permitting free expansion, thus avoiding leakage at the joints.

Brisk circulation of water promoted by upright tubes and suitably arranged return tubes, steam bubbles escaping freely to the upper drum.

Perfect control of the amount of superheat.

General simplicity in design, and therefore great reliability.

The Yarrow Land Boiler.

This boiler (manufactured by *Messrs. Yarrow & Co., Ltd., Glasgow*), fig. 31, consists of three or more drums, including a saturated steam drum of large capacity, which is connected to each of the water-drums by straight tubes. The drums are of circular section, built up of pressed steel parts, the shell generally being in one ring, so that no intermediate circumferential joint is required. The drum ends are of partial spherical form, and no stays are necessary. For higher pressures, as in the case of Yarrow Boilers adopted in many recent installations, the drums are made from hollow forgings, either entirely seamless, or with riveted joints only where separate ends are attached. The tubes in both the superheater and the boiler are expanded into thickened tube plates and bell-mouthed at their ends. The tube plates on the inside of the drums are, where necessary, recessed out in way of the tube holes, to enable the expanding of the tubes to be perfectly carried out. The Yarrow boiler is supported by the steam drum being slung from a strong steel structure, which leaves the tubes and water-drums perfectly free to expand independently.

As one of the water-drums is placed at the front of the furnace and another at the back of the furnace, the tubes joining these drums to the steam drum are adjacent to the furnace. It is well known that, owing to direct radiation, by far the greater part of the heat utilised in a boiler is transferred in the tubes nearest the fire. From the above it will be realised that as so large a proportion of the heating surface is adjacent to the fire, the total heating surface of the Yarrow boiler for the same output and efficiency can be considerably less than is usual.

Another characteristic of the Yarrow boiler is the very rapid circulation through the tubes due to their being straight and nearly vertical.

An outstanding feature of this boiler is the complete absence of any form of baffle or obstruction in the path of the gases where dirt could collect. This feature can be readily seen from fig. 34, which shows the cross section of a Yarrow boiler with superheater as arranged when the flue gases are discharged into a common flue at the back of the boiler.

The Yarrow type of superheater consists of a single mild steel drum into which inverted **U** tubes are expanded. Suitable internal divisions are fitted in the drum so that the required number of passes through the **U** tubes can be obtained. This form of superheater is self-draining.

The Yarrow boiler is often arranged with a damper in the flue above the side of the boiler on which the superheater is situated (see also description of Yarrow marine type boiler, page 2391), and by means of this damper all the gases can be made to pass up the side of the boiler remote from the superheater. This arrangement forms a convenient method of controlling the degree of superheat which can be reduced almost to a minimum without causing a serious falling-off in the steam-raising capacity or efficiency of the boiler.

In order to clean the interior of the boiler it is only necessary to remove the manhole door from each drum end (each is secured by two bolts). A man has ample room in the saturated steam drum for operating the tools for cleaning the inside of the tubes. For cleaning the outside of the tubes where this cannot be conveniently done from the furnace, access doors are provided in the side and end casings.

Owing to the great height of the furnace and to the large area between the tubes in the furnace rows, or, in other words, the low velocity of gases passing out of the furnace, the Yarrow boiler is found to remain comparatively clean after long periods of steaming. This, coupled with the fact that there are no places on which dirt can lodge, are the chief reasons why the efficiency of the Yarrow boiler does not fall off as in some other types.

For Electric Power Stations where peak loads have to be provided for, the Yarrow boiler is particularly suitable, as it cannot be damaged by too quickly increasing the rate of evaporation, and it can be forced to almost any extent without fear of damage. It is sometimes fitted with feed-water economisers or air-heaters, and sometimes with both. The general design of the boiler lends itself to making a compact and accessible unit when combined with these adjuncts.

FIG. 34.

BOILER SETTING.

In ordinary practice, as developed by long experience, a boiler (figs. 35, 36, 37) is set upon two longitudinal walls, parallel to one another, and distant apart over half the diameter of the boiler. On these walls are laid specially formed seating blocks (fig. 38) of firebrick, the seating edge of which should not exceed 3 inches in width, and may advantageously be convex in

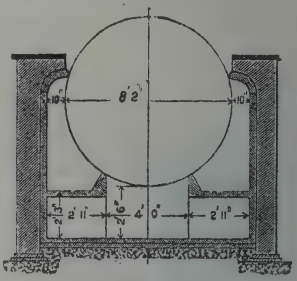

FIG. 35.

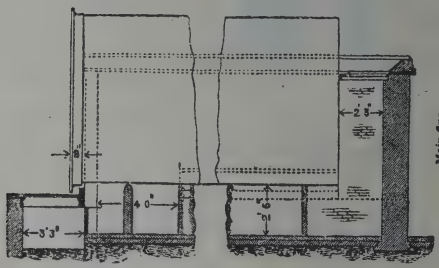

FIG. 36.

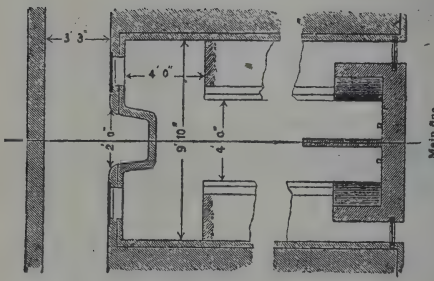

FIG. 37.

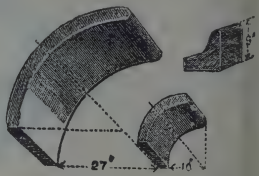

FIG. 38.—Flue Covers and Seating-block.

profile so as to touch the boiler plate along a line only. Where the ring seams cross the seating blocks, a rectangular gap should be cut across the seating for purposes of inspection, and specially formed wedge pieces ought to be provided to close these gaps. These are removed for inspection and at once replaced.

Properly designed fireclay blocks for the seating and downtake allow for expansion and contraction, and minimise air leakage. This is important, as air leakage often accounts for 5 per cent. of the coal bill. Lancashire boilers can be made to work practically airtight.

Foundations.

In preparing the foundations, a matter of great importance is that good drainage should be ensured, as it is found that serious damage often occurs to boilers owing to dampness which arises from the foundation, such outside wasting not being caused by leakages from the boiler itself, but simply from being built either on wet ground or where surface water is allowed to accumulate. Care should also be exercised that the foundations are built in hard well-burned bricks.

It is often advisable to concrete the whole area under the boiler and flues.

It is frequently specified that the internal parts of the flues should be lined with firebricks. For boilers of the Lancashire type, experience shows that this is an unnecessary expense. Good quality hard bricks are satisfactory, the only firebricks used being the specially shaped seating blocks in contact with the boiler shell and those for the bridge at the back of the grates.

Where in contact with the boiler shell, the bricks must be set in fireclay. Elsewhere ground mortar (three parts of ashes to one of lime) may be used.

The boiler should be set having a fall of about 1 in 240 towards the front end, so as to ensure its being thoroughly drained of its contents when it is emptied for its periodical cleaning. The top of the side flues also should be made up by flue covers (fig. 38) of fireclay, in such a form as generally to allow a flue of about 10 inches at each side of the boiler, the flues themselves being of such dimensions as will allow of a man getting thoroughly round for the purpose of cleaning and examining the boilers from time to time.

The following materials are required to seat a boiler 7 feet in diameter by 30 feet long :—

Firebricks and bricks for flue lining, including breakage	6,000
Downtake covers 6 inches wide	14
Seating blocks	52
Flue covers, 12-inch wide	64
Fireclay and ground mortar	3 tons
Common bricks for external walls	Quantity varies according to thickness.

Mortar for laying up firebrick is too often made of fireclay alone. This is very bad practice for the reason that a mortar made of fireclay alone has no permanent body, and after it has been subjected to heat for some time it crumbles from between the bricks. A satisfactory mortar for this purpose may be made by mixing ½ ton of fireclay and 1 ton of firebrick dust (crushed firebrick) to the proper consistency, for each 1,000 firebricks laid. The brick dust, or crushed firebrick, should be the size of a pea and smaller. This mortar, when set, forms a compact refractory binding that is as strong as the brick itself.

Some Modern Improvements.

When preparing the foundations for a boiler or battery of boilers, it is essential that the position chosen be carefully examined, for if the situation is at all damp or there is a liability of the surrounding ground getting soaked with surface water or floods, a proper system of drainage must be adopted. For this purpose an experienced engineer should be consulted. Also where the ground is of a sandy or shaley nature it may be necessary to resort to piling, and as there is no general rule to follow, experience can alone decide the laying out of the work. It is essential that there should be no sinking or warping of the foundations, which not only hastens the formation of cracks in the settings, but induces strains in the pipe work and causes other serious inconveniences.

Most boiler makers supply a general plan of the brickwork setting, which is usually of the old type, and shows broad-faced blocks and semi-circular covers in contact, with two or three courses of brickwork on top. It is far better, however, to have one's own carefully prepared drawing made for the specific installation, prepared by some firm of repute which makes a speciality of this class of work and approved by the engineers and the Boiler Insurance Co.

After the foundations are laid and brought up to the level ready for commencing the boiler setting proper, it is well sometimes to allow several days to elapse to ensure that there will be no further settlement, especially where concrete has been employed.

In the ordinary type of Lancashire boiler the path of the gases, after leaving the boiler flues, is along the bottom flues to the front, and then dividing to the side flues they pass thence into the main flue through separate dampers. There are many instances in which the gases pass first through the side flues and then along the bottom flue to the main. This system is not to be recommended, as the hottest gases should first pass under the boiler. As to the dimensions of the flue passages, these are a compromise, small flues giving difficulty when inspecting, while large

flues add too much useless surface. The back downtake should not exceed 2 ft. 6 ins. from back to front, the sides tapering from the width over the furnace tubes to about 3 ft. 6 ins., and not exceeding 4 ft., with a depth of from 3 ft. to 4 ft., depending upon the size of the boiler. It is usual now to give a greater width in the downtake in order to accommodate if necessary a superheater without requiring too much reconstruction. The side flues are made with vertical sides giving 9 to 12 ins. clear from brickwork to boiler plates at the centre line of diameter, and the floor level being about on a level with the bottom of the boiler gives a convenient chamber for an inspector to crawl through, while providing ample space for the accommodation of soot.

With the Paxman 'Economic' type of boiler (page 1644) the arrangement is somewhat different. The gases pass from the main iron flues into the back chamber where they divide right and left and return through the internal boiler tubes into two front smoke boxes from whence they pass downwards to two underneath flues separated by a mid feather upon which the boiler rests. These flues meet at the back, and the products of combustion pass out through a single damper or dampers to the main flue.

A number of firms make special firebrick blocks for boiler setting. These include mid feather and side seatings, large and small segment blocks for the top of the side flues and back chamber, besides flat blocks and other shapes less commonly employed but often required. However well the brickwork, as constructed on the older plan, may be cemented together, the constant movement of the boiler under steam and the changes of temperature soon begin to cause cracks and crevices to appear, especially between the boiler shell and the brickwork. The result is a loss of draught and short circuits in parts of the flue causing a considerable reduction of thermal efficiency. Further, the blocks being cemented in position the work of the boiler inspector, who has to thoroughly examine the boiler plates on the outside, is not an easy one, and to remove the permanent brickwork entails a very considerable amount of trouble and expense.

Cushioned Seating Blocks and Covers.

The 'Pearson Patent' Asbestos Cushioned Seating Blocks and Flue-Covers (*E. J. & J. Pearson Ltd., Stourbridge*) have been specially designed to remedy sources of waste caused by (*a*) corrosion of the plates, due to the presence of moisture in the brickwork; (*b*) short circuiting of the hot flue-gases; (*c*) leakages of cold air into the flues; and at the same time to be readily removable and replaceable when an inspection has to be made.

The arrangement, as shown by figs. 39 and 40, consists of a specially prepared cushion of hard asbestos, compressed into a groove formed on the face of the blocks, in such a way that the boiler-plates are completely insulated from all contact with the blocks themselves.

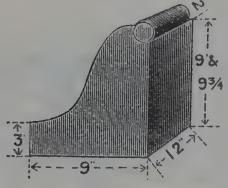

Fig. 39.—Patent 'Asbestos Cushioned' Seating Block.

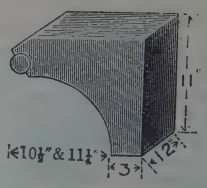

Fig. 40.—Patent 'Asbestos Cushioned' Flue-Cover.

The plates are thus secured against the rubbing caused by the expansion and contraction of the boiler, and also against any risk of corrosion through contact with damp brickwork or blocks which alone has been the cause of very many serious explosions.

Owing to the non-absorbent nature of the material, and also to the high pressure to which it is subjected, the hard asbestos-cushion does not take up moisture, as is the case with ordinary clay blocks, consequently there is no possibility of corrosion. No corrosion has ever been found in boilers set with these seatings, and boilers can be inspected which have been running for several years. In addition to this advantage, the presence of the compressed asbestos cushion ensures an absolutely gas-tight joint between the boiler plates and the blocks, so that not only is there no risk of any short circuiting of the flue-gases, but (an even more important consideration) no danger of cold air finding its way into the flues from the outside, there being no necessity to fill up large spaces with ashes or sand in order to ensure air-tightness. The arrangement gives a

specially large heating surface. Under the old system, 10 per cent. of the external surface of the boiler was covered up by, and in contact with, brickwork; while in a boiler set with the Patent Asbestos Cushioned Blocks, less than 1 per cent. of the external surface is covered, and at no point are the seating blocks or covers in contact with the boiler plates.

The 'Patent Asbestos Cushioned Seam-Inspection Blocks and Covers' (figs. 41 and 42) are designed to meet the requirements of the Board of Trade and the insurance companies. The Board of Trade now require a proper inspection at least once in fourteen months, and the removal of the brickwork, wherever necessary, is compulsory. These blocks enable complete examination of the ring-seams, without any need to remove more than the block or cover opposite the seam. This means a great saving of time and expense at each inspection. The lower half of the block is built and bonded into the side wall of the flue, rendering it a part of the permanent structure, and enables the upper half to be removed with utmost ease, admitting daylight to the flues and

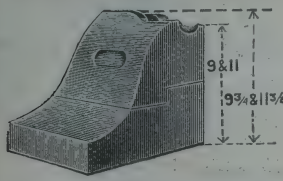

FIG. 41.—Patent 'Asbestos Cushioned' Seam-Inspection Seating Block.

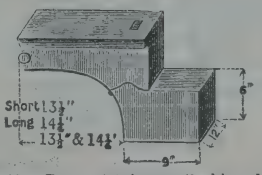

FIG. 42.—Patent 'Asbestos Cushioned' Seam-Inspection Flue Cover.

facilitating inspection. The upper part of the block turns slightly on the knuckle joint, and is thereby safe from cracking under boiler expansion. Handholes are inserted in upper half of each cover for lifting purposes.

It is probable that no part of a boiler setting of the old types gives more trouble than the back downtake. The constant expansion and contraction of the boiler causes the blocks or slabs, used to cover in the downtake flue, to crack and fall down into the flue. The 'Pearson Patent Interlocking Downtake Arch' (fig. 43) is an arrangement of great simplicity and reliability. It consists of an arch, of the required span, built up of interlocking bricks, so shaped that while

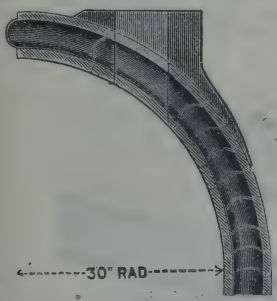

FIG. 43.—'Pearson Patent Interlocking Downtake Arch.'

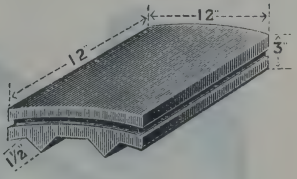

FIG. 44.—'Angular Contact Slab.'

they are as easily built up as an ordinary brick, when once in place they cannot be dislodged, and however much the arch may give to the movements of the boiler, no displacement of the brickwork can occur. Each set is fitted with two manhole blocks with lids, by means of which easy access is obtained to the flues, without disturbing the brickwork.

For the covering in of the boiler the 'Angular Contact Slabs' (fig. 44) may be used. In these coverings, advantageous use is made of the well-known fact that an envelope of stationary air is one of the best non-conductors of heat known.

Recent tests, of which particulars are given below, show the efficiency of this method of covering, there being a difference of over 90° C. between the temperature under the covering and the external air temperature.

Tests.

(1.) Report on test of Angular Contact Boiler Covering Slabs with layer of hair felt between slabs and boiler plates :—

Type of boiler, 'Lancashire'	30 ft. × 7 ft. dia.
Working pressure at time of test	40 lbs.
Temperature of atmosphere	8° C.
Shaded temperature taken 3 ins. above surface of bare boiler shell	83° C.
Shaded temperature taken 3 ins. above surface of covering slabs	21° C.
Temperature under covering slabs	107° C.

Boiler housed in shed open both ends.

(2.) Report on test of Angular Contact Boiler Covering laid on boiler shell without felt or silicate cotton :—

Type of boiler, Cylindrical	26 ft. × 6 ft. 6 ins. dia.
Working pressure at time of test	40 lbs.
Temperature of atmosphere	10° C.
Shaded temperature taken 3 ins. above surface of bare boiler shell	81° C.
Shaded temperature taken 3 ins. above surface of covering slabs	15° C.
Temperature under covering slabs	109° C.

Boiler set in the open and not housed.

The covering slabs are quite distinct, and have no connection with the flue-covers, the compressed asbestos cushion preventing any leakage of flue-gases : consequently while radiation of heat from the boiler is prevented, there is also no possibility of the temperature under the slabs being raised by the infiltration of hot flue-gases.

The covering slabs form a surface hard enough to be worked on, and can easily be removed for the inspection of the boiler plates at any time, and as easily replaced, the covering being in no way damaged by the removal.

The 'Karrena' Furnace Roof.

(*A. B. Cleworth & Co., Ltd.*, 118 *Queen Victoria St., London, E.C.* 4.)

The principle of the 'Karrena' roof, fig. 45, consists of specially shaped refractory blocks, suspended between hollow prismatic girders, arranged either transversely or longitudinally to

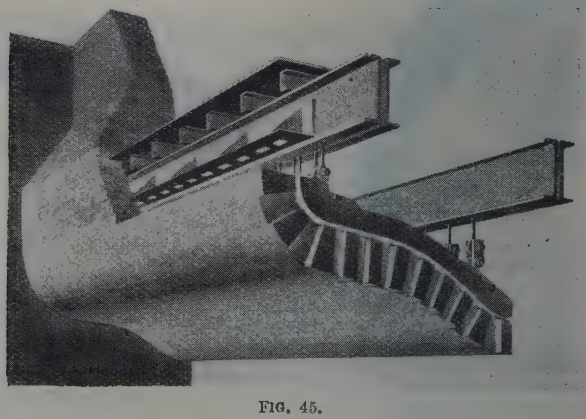

Fig. 45.

the grate. The shape of the girders and the necks of the blocks renders it impossible for the latter to slip or subside, and all sharp corners (which may be the cause of cracks) in these blocks are avoided.

The refractory blocks in the 'Karrena' roof, being suspended, there is no outward pressure exercised on the side walls, as is the case with a sprung arch, and consequently the side walls need not be of such heavy construction. Further, owing to the absence of pressure between the suspended blocks themselves, their life is considerably increased.

The construction of the 'Karrena' roof enables it to be erected in practically all furnaces in one span, thus, in two stoker boilers, eliminating the middle wall, and thereby increasing the volume of the furnace, giving more even heat distribution throughout the whole width of the combustion chamber. Furthermore, the 'Karrena' roof being flat, the radiation of heat over the grate is evenly distributed over its whole width, which ensures best utilisation of fuel and improved combustion.

An important advantage possessed by the 'Karrena' system of roof is that the sweep or curve in the longitudinal section of the roof can be designed to suit any conditions, and the incline in the roof can be altered, *i.e.* raised or lowered, without any dismantling.

The 'Liptak' Flat Furnace Arches.

(*Liptak Furnace Arches, Ltd.*, 38 *Victoria Street, London, S.W.* 1.)

The Double Suspension system of constructing Flat Furnace Arches (fig. 45A) as patented and supplied by Liptak Furnace Arches, Ltd., provides a renewable working face with ample protection for the ironwork.

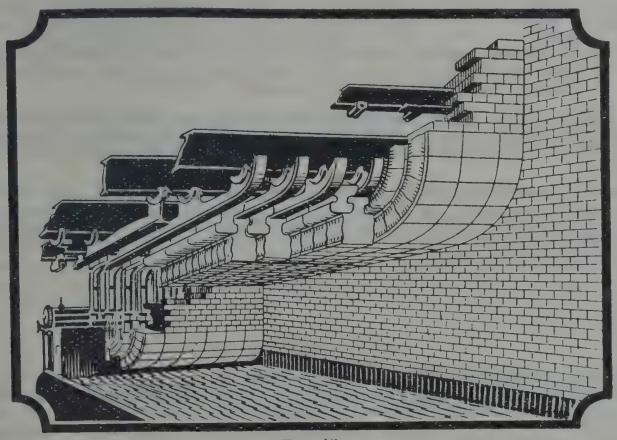

FIG. 45A.

The blocks of the working face are readily renewable, as the lower blocks are suspended from an upper arch of refractory material, so that if the whole of the lower blocks were burned away there would still be refractory protection between the furnace heat and the ironwork.

The arches have been supplied in large numbers in this country and in widths up to 26 ft. between walls.

Liptak Furnace Arches, Ltd., are also makers of air-cooled refractory walls for combustion chambers, and single suspended arches for industrial furnaces.

Leaky Boiler Settings.

Leakage through boiler settings of brick can be lessened by giving the walls two coats of Portland cement wash and then one coat of cold water paint to brighten them up. Or the brick settings may be sealed by applying cement with a covering of canvas pasted over and then painted.

Another method is to build with mortar in which a certain quantity of cement has been mixed, the amount to be gauged by the tenacity of the mortar, which must not hold bricks so that they will be destroyed if it is found necessary to take the brickwork down : a 5 per cent. cement will give this, but may be increased or decreased ; the greater the percentage of cement the tighter the setting, but with the above disadvantage.

Washing the bricks with the liquid cement when building will give best results ; the brickwork should then be coated with the thin pure cement liquid afterwards, the cement being used as a wash. (*Horobin.*)

Bramwell Automatic Expansion Joints for the Fronts of Boilers.

When a boiler which is seated on brickwork, such as a Lancashire boiler, expands, the brickwork is crushed to a certain extent. In time slight crevices appear where the boiler is in contact with the brickwork. At the front of the boiler these crevices admit cold air into the side and bottom flues, lowering the flue gas temperature and reducing the efficiency of the boiler.

The Bramwell expansion joints are designed to stop this leakage without interfering with the structure of the boiler or its working in any way.

An 'L' section casing is fitted to the brickwork round some two-thirds of the circumference of the boiler, and an airtight joint is made between this casing and the brickwork.

Inside this casing is a ring of asbestos, which is made to maintain an airtight joint with the boiler shell by means of a wire rope, passing all round inside the casing, pressing against the back of the asbestos, and held tight by weights acting through a lever and pulleys. A joint is then made between the asbestos and the casing by screws at intervals, which draw the asbestos against the casing, tight enough to make a joint, but not tight enough to prevent the wire rope forcing the asbestos forward when the boiler contracts.

The whole device is flexible, and not affected by any irregularity of the circumferential expansion of the boiler, nor is the joint broken by the longitudinal expansion. Moreover, the sliding joints are made between metal and asbestos, and a fixed joint only is made with the brickwork.

The second part of the joint is an airtight door over the blow-off chamber. The door is split vertically to provide for the blow-off pipe, and is screwed down against asbestos packings when in position. It can readily be removed for inspection, but when in place the door completely excludes cold air, not only from the bottom flue by stopping leakage, but also from the surface of the boiler shell in the chamber.

Fusible Boiler Plugs.

There are six primary causes for the rejection of fusible plugs, which may be roughly divided into two classes. Under the first class, rejections are included due to mechanical defects of casing material. The second class includes rejections due to lack of purity in the tin filling. The impurities in the latter case may be those either present in the original tin or those introduced during the manufacture of the plug.

The following conclusions have been reached as to the precautions to be taken in the manufacture of fusible plugs :

1. The pig tin should be at least 99·7 per cent. pure, containing not more than 0·1 per cent. lead, or 0·1 per cent. zinc, which are the requirements of the Steamboat Inspection Service.

2. The casing should be of bronze, an alloy the major constituents of which are copper and tin. Small amounts of zinc and lead increase the ease of casting and machining, and are not objectionable if not present in greater amounts than in the following compositions :

	I.	II.
Copper	88	87
Tin	10	7
Zinc	2	5
Lead	—	1

3. The pot or crucible for melting the tin should not be used for melting other metals, thus doing away with the liability of contaminating the good tin when these are not thoroughly cleansed.

4. Casings should be tinned on the inside with the same grade of tin used for filling, but the tin left over from this process should not be added to the filling to be used. Zinc-chloride flux may be used, although hydrochloric acid is preferred, though no flux need be used during the filling process.

5. The casing should be preheated to not above 250° to 275° C. (482° to 527° F.), and tin should be poured at a temperature not above 275° to 300° C. (527° to 572° F.).

('*Bulletin of the American Institute of Mining and Metallurgical Engineers.*')

In order that fusible plugs may fulfil the important function of safeguarding boiler flues from collapse in the event of shortness of water, it is essential the following conditions should be complied with:—

1. The fusible plug should be of an efficient and approved type. Common plugs are of little or no service.

2. The fusible plug should be kept clean both on the fire and water side.

3. As the nature of the fusible alloy is affected by prolonged service, the fusible alloy should be renewed after it has been in service for twelve months. Spare caps should be kept to facilitate this operation and the used cap returned for refilling.

4. When used plugs are refilled, the old fusible alloy should be removed and the surface of the shell scraped bright, and properly tinned and refilled with new alloy. Fusible plugs should not be refilled with used metal.

5. The fusible alloy must be a properly graded mixture such as research and experience has shown to be necessary. ('*Vulcan*,' *Oct.* 1920.)

CHIMNEY AND FLUE DIMENSIONS.

Apart from any consideration of production of draught, the height of a chimney must be such that the smoke and noxious gases are discharged at a level at which they will not be a nuisance. The minimum height is usually fixed by the bye-laws of local authorities.

For relation between draught in inches of water gauge and chimney height see page 1606.

The area of the chimney depends on the amount of coal burned per hour on the grates of the boilers which it serves, and on the velocity of the gases in the chimney, and their temperature.

The gas velocity again depends on the draught pressure, and on the frictional resistances in the flues and chimney. Thus the area of the chimney for a given size of boiler or battery of boilers should take into account many factors, some of which are not capable of exact determination. This accounts for the empirical character of the rules given by various authorities, and for the variations in them.

For typical conditions, say about 600° F. chimney temperature, flues not abnormal in length, and of area about 20 to 40 per cent. greater than chimney area, and 25 to 28 lbs. of coal burned per sq. ft. of grate area per hour, the following rules give suitable areas:—

H = height of chimney in feet; A = area at top of chimney in sq. ft.; G = grate area.

$$A = \frac{k\,G}{\sqrt{H}};$$

where $k = 1{\cdot}5$ for one boiler, $1{\cdot}0$ for two, $0{\cdot}8$ for three, $0{\cdot}7$ for four, $0{\cdot}5$ for five or more.

At 28 lbs. coal per sq. ft. of grate area per hour this corresponds to

$$A = \frac{k\,W}{28\sqrt{H}};$$

where W = lbs. coal burned per hour.

For a 100-ft. chimney, and $k = 1{\cdot}4$,

A = 0·5 sq. ft. per 100 lbs. coal burned per hour.

Other formulæ are:

(*a*)
$$A = \frac{W}{14\sqrt{H}}$$

evidently for lower rate of combustion than the above, as it would agree with $k = 1{\cdot}5$ and rate of combustion 21).

(*b*) Area in sq. in. $= \dfrac{\text{lbs. coal per hour} \times 12}{\sqrt{H}}$ . . . . (*Bourne*).

or $A \text{ (sq. ft.)} = \dfrac{W}{12\sqrt{H}}$.

(*c*) Area in sq. ins. = 1·5 per lb. coal per hour . . . (*Bourne*).

or $A = \dfrac{1{\cdot}5}{144} W$

(corresponding to $k = 1{\cdot}5$ if H = 100 and combustion rate = 14·4).

(*d*) Area in sq. ins. $= \dfrac{\text{Area of grate}}{\sqrt{H} \times 1{\cdot}58}$ . . . . . (*Elswick*).

or $A = \dfrac{1}{1{\cdot}58} \dfrac{G}{\sqrt{H}}$

(corresponding to $k = 0{\cdot}63$).

(*e*) Kent gives formulæ which correspond to the following :—

$$\text{Effective area } E = A - 0{\cdot}6\sqrt{A};$$

$$W = 16{\cdot}65\, E \sqrt{H}; \qquad D = 13{\cdot}54\sqrt{E} + 4;$$

$$E = \frac{0{\cdot}06\, W}{\sqrt{H}} \qquad S = 12\sqrt{E} + 4$$

where,

D = diam. of round chimney in inches ; S = side of square chimney in inches.

The table on page 1674 has been calculated from the foregoing formulæ of group (*e*).

(*f*) Sometimes the area of the chimney top is taken as $\frac{1}{8}$ to $\frac{1}{10}$ that of fire grate, the height not being taken into account.

Flue areas should be about 20–40 per cent. greater than chimney area.

For stability of chimneys see Section XII, page 623.

SUPERHEATERS.

Separately fired superheaters are not often used ; the superheaters are usually integral with the boiler in the case of water-tube boilers, or placed close to the boiler, in the downtake flue, in the case of the Lancashire type.

The steam may pass through the tubes in parallel—single-flow—or some of the tubes may be in series with the rest—multiple-flow type. The multiple-flow type gives a higher rate of flow of steam in the tubes for the same tube surface. The heat transmission is thus increased, and a higher degree of superheat obtained. There is, of course, a slightly greater drop of pressure in the multiple-flow type.

The superheat added to the steam depends upon :—

1. The heating surface per pound of steam per hour.
2. The temperature difference, gas to steam.
3. The velocity of the steam in the superheater.
4. The velocity of the hot gases past the tubes.
5. The pressure of the steam.

Factor 2 is very difficult to predetermine accurately, and hence superheaters are still mainly designed by rule-of-thumb. Modern superheaters are frequently so made that the steam velocity can be altered, thus permitting an adjustment if an incorrect estimate has been made. There are two principal methods of altering the velocity : by plugging up tubes, or removing them, and by rearranging the proportion of tubes in parallel to those in series. The first method is of practically no value.

Factors 2, 3 and 4 change with the amount of steam used, as with the load. The effect of load on factor 2 (temperature) is more marked the farther the superheater is from the grate,

and is very marked if in the downtake of a Lancashire boiler for instance. Factor 2 is also very much dependent on the normal rate of firing and the quality of coal used. Thus with poor coal a superheat of 100° F. at full load may fall to 30° F. at half load. If the normal rate of firing is high or the quality of coal good, the change of loading has less effect.

Superheaters are designed chiefly with regard to practical considerations, such as standardisation of tube lengths, convenience of access to individual tubes or elements, and ease of repair.

Heating Surface of Superheaters.

As a rough approximation, the heating surface may be calculated on the assumption that the heat transmission is at the rate of 5 B.Th.U. per hour per sq. ft. of heating surface per °F. of the difference of the arithmetical mean temperatures of gas and steam.

If W = steam generated in lbs. per hour;

H = heat required to superheat 1 lb. of steam (see Table IV, p. 1597);

T = mean gas temperature;

t = mean steam temperature;

then heating surface in sq. ft.

$$= \frac{W \times H}{(T - t) \times 5}$$

For example:—Let W be 6,000 lbs. per hour, the pressure 160 lbs. per sq. in., and superheat 200° F. The saturation temperature is 371° F., and final steam temperature 571° F., so that $t = 471°$ F. H (from Table IV) = 110 B.Th.U.

Assuming a Lancashire boiler, with the superheater placed in the downtake, the value of T may be 950° F., the heating surface $= \frac{6{,}000 \times 110}{(950 - 471) \times 5} = 276$ sq. ft.

The ratio of the heating surface of the superheater to that of the boiler varies very widely, even for boilers of the same type. It is difficult, therefore, to give typical figures. The following are taken from examples of actual practice, the ratio being expressed as a percentage of the boiler heating surface (excluding the economiser).

The ranges shown do not necessarily give the limiting values.

Lancashire boiler, superheat	150° F.	17 to 24 per cent.
,, ,, ,,	200° F.	25 to 28 ,,
Water-tube, Babcock . . .		15 to 40 ,,
,, ,, Stirling . . .		13 to 15 ,,
,, ,, Yarrow . . .		12 to 28 ,,
Locomotive		about 22 ,,

Boilers with superheaters require a smaller heating surface to give a desired efficiency.

Even if the amount of heating surface is calculated with due allowance for the effect on the heat transmission rates of the actual steam and gas velocities, it will be found that different rates of steam flow do not greatly alter the calculated heating surface. It is important to recognise, however, that at low steam rates the tube temperature becomes higher.

Sectional superheaters are arranged so that individual tubes or small groups of tubes may be readily removed without putting the whole superheater out of action.

The McPhail & Simpson Patent Superheater.

(*McPhail & Simpson, Wolverhampton.*)

The headers and tubes of these superheaters (fig. 46, p. 1677) are of solid drawn wrought steel.

The simple construction, and high-class material and workmanship used in their construction, render the superheaters absolutely steam tight, and at the same time ample means are provided for getting at the tubes should they by any chance require attention. This is made possible by the provision in the headers of the patent stoppers opposite the ends of each tube, whereby easy access to the tubes is obtained for expanding, examination, etc., and any individual tube can be

THE MCPHAIL & SIMPSON PATENT SUPERHEATER.

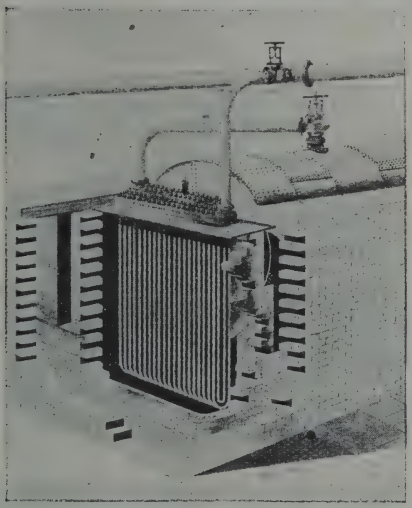

FIG. 46.

THE 'GALLOWAY' SUPERHEATER.

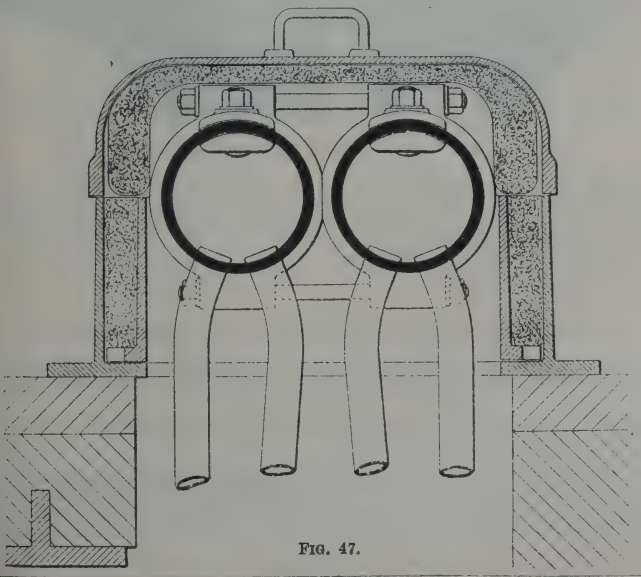

FIG. 47.

removed and replaced in a very short time, without disturbing the other tubes or pipe connections and without breaking a large joint.

There are no studs and no large joints used in these superheaters.

The substantial nature of the tubes entirely prevents warping.

The superheaters are adaptable to any type of boiler—Lancashire, Cornish, Babcock—and all types of water-tube boilers, both land and marine, and for independent firing.

Flooding of the superheaters, or the use of dampers, is not recommended.

Galloway Superheaters.

(Galloways, Ltd., Knott Mill Ironworks, Manchester.)

The Galloway Patent Multiple-Flow Superheater.

This superheater (figs. 47 and 48) is made entirely from mild wrought steel. All parts are of circular cross-section and therefore of maximum strength. There are three headers—two short ones, with the inlet and outlet branches, and one long one closed at both ends. The headers are rigidly stayed together to prevent movement and vibration, and are connected by the tubes, which are of seamless steel. The tubes are in groups of four or five, each group commanded by an internal cap so as to facilitate inspection and cleaning. The steam passes from the short inlet header through the first set of tubes into the long header, and then through the second set of tubes to the short outlet header. The headers (fig. 47) are carried in a double-walled box resting on the brickwork and covered by a cast-iron cover, thus minimising radiation losses and protecting the superheater from weather and damage.

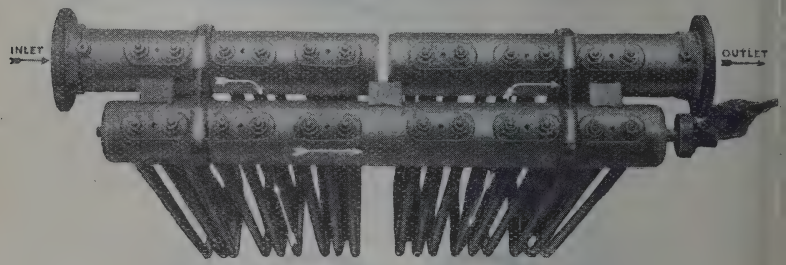

Fig. 48.—Plan view of Superheater showing direction of Steam Flow.

The joints between the superheater and the main steam piping are vertical, thus enabling the superheater to be removed for inspection without disturbing the steam pipes. If it is desired to work with the superheater removed, a straight connection or cross-over pipe is inserted in its place.

The superheat usually attained is 150° F. to 200° F. with ordinary firing.

The Galloway Patent Sectional Wrought Steel Steam Superheater.

To meet the demand for a superheater with tubes arranged so that they may be readily and quickly detached without disturbing the other tubes, *Galloways Ltd.* have designed and patented a sectional type superheater of simple and durable form.

The sectional type superheater is for use in the downtake flue at the rear of Lancashire and Galloway boilers, or for independent firing.

As shown (fig. 49) the superheater consists of two horizontal steel headers placed parallel to each other. A series of holes are drilled and faced for joints on the upper walls of the headers, to which the small steel boxes or hollow connecting chambers are secured by means of two studs of ample strength.

The superheater tubes are solid-drawn weldless steel of loop type or U shape, and the outside diameter of the tubes is 1½ ins. The ends of the tubes, which are straight and not bent over (thus maintaining full thickness and strength), are expanded into the under walls of the connecting chambers, usually in groups of three.

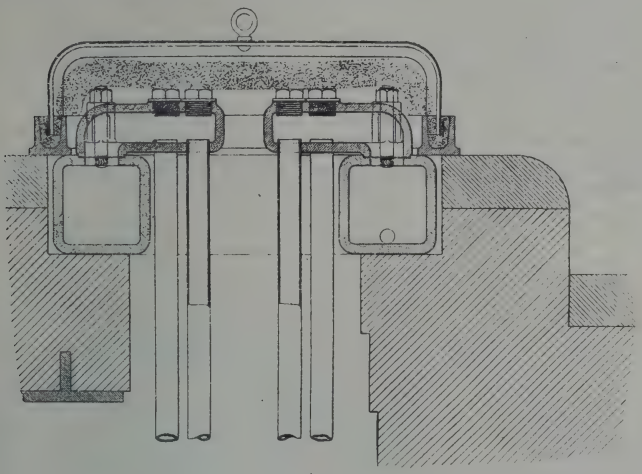

FIG. 49.

The upper walls of the connecting chambers are provided with screw plugs disposed in alignment with the ends of the several tubes, so as to give free access to the end of any tube for the purpose of examination or expanding without interference with or obstruction from the studs securing the connecting chambers to the headers.

Any of the groups or elements of superheater tubes, which are interchangeable, can be readily removed and replaced, or alternatively 'blanked-off,' by simply unscrewing the four securing studs of the two connecting chambers, and without disturbing any of the other groups of tubes or the main steam headers.

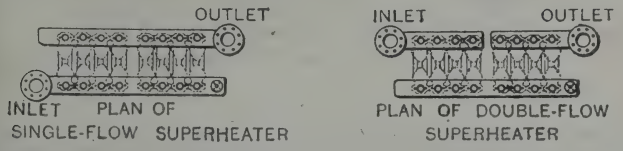

FIG. 50.

The superheater (fig. 50) is made either single-flow or double-flow, the latter type being adopted for higher degrees of superheat.

The single-flow type has headers of equal length, and the steam has only a single pass through the tubes.

The double-flow superheater is similar in construction, with the exception that one of the headers is divided in its length to form two separate headers.

The steam is passed from the short inlet header, by way of the first nest of tubes, into the long header, and then through the second nest of tubes into the short outlet header.

The Babcock & Wilcox Standard Integral Superheater.

(Babcock & Wilcox, Ltd.)

The Babcock & Wilcox Patent Steam Superheater (fig. 51) consists of solid-drawn steel tubes bent into **U** shape, and connected at both ends with boxes or manifolds (F and H), one of which (F) receives the natural steam from the boiler through the dry pipe (N) and inlet pipes (D). The other (H) receives the superheated steam after it has traversed the superheater tubes (G), delivering it through pipes (J) and cross-box (K) to the stop valve (L) placed above the cross-box. Handholes are placed in the manifolds opposite the ends of the superheater tubes to facilitate inspection.

The superheater is placed in a position where there is practically no deteriorating condensation of the gases, and where the temperature is sufficiently high to ensure the steam receiving from 100° to 300°F. of superheat, or more if desired. It is not subject to the immediate action of the fire, as the furnace gases must first pass through the front part of the boiler, which comprises a considerable heating surface. Assuming the boiler to be in regular work, and the firing even, no

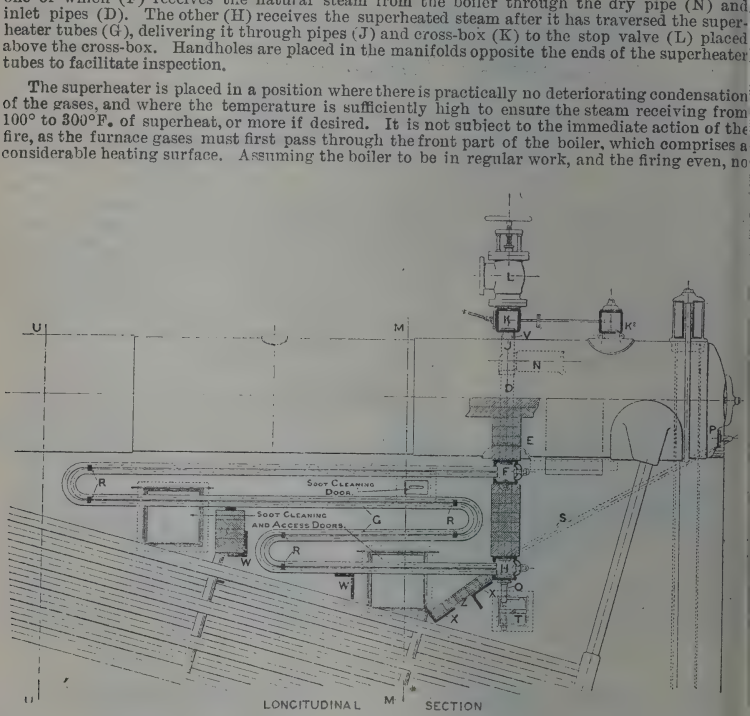

Fig. 51.

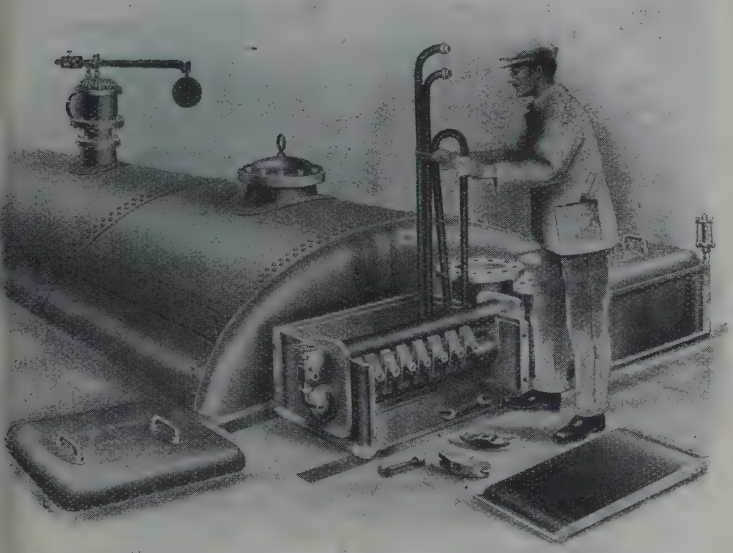
great fluctuations in temperature can take place where the superheater is fixed. It is readily accessible for examination, and for the renewal of tubes. There are no flanged joints, all the tube joints are expanded. Expansion is provided for by the tubes being free at one end, and by the manifolds not being rigidly connected with each other. Prevention against over-heating during steam raising from cold water after cleaning, etc., is ensured by the arrangement for flooding with boiling water, and using the superheater as part of the boiler-heating surface.

The flooding arrangement consists in a connection with the water space of the boiler drum; by means of the larger of two cocks (B) and connecting pipe (S) water can enter the lower manifold (H) and fill the superheater to the water level of the boiler. Any steam formed in the superheater tubes is returned into the boiler drum, through the collecting pipes (D), which, when the superheater is at work, convey saturated or natural steam into the upper manifold (F). Prior to opening the stop valve (L), when a superheater has been flooded, the water is drained away from the manifolds by the pipe (O) and the smaller cock (C). A sight glass (A) is attached to the outlet of the small cock to show when all the water has been blown out.

Very considerable economy is obtained by the use of superheated steam, and present practice in Central Station work is to use steam of the high temperature of 700° F.

'UNIT' Superheaters

The most efficient and accessible Superheater on the market, and manufactured to suit every type of boiler.



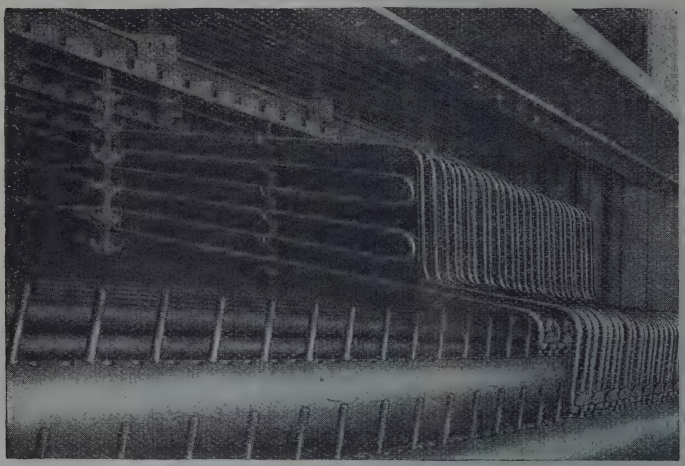
Each Tube Element is detachable. All parts interchangeable.

Head Office:

'UNIT' Superheater & Pipe Co., Ltd.

UNIT WORKS, SWANSEA

Also manufacturers of **Solid Drawn Steam Pipes**, in weldless steel, for High Pressure and Low Pressure mains. Enquiries solicited—prompt deliveries.



M.L.S.' HIGH DEGREE SUPERHEATER
(Inter Deck Design)

SPECIAL ADVANTAGES :

1. Fewer joints to be kept steam tight.
2. Type of joint proved most efficient for high pressures and temperatures.
3. Return Bend made by Patent 'M.L.S.' Integral Machine Forged Process.
4. Headers and joints are outside the boiler setting.
5. Uniform distribution of steam at all loads.
6. Highest heat transfer rate without objectionable cores.
7. Soot troubles and draught losses reduced to minimum.
8. Very little weight on boiler tubes.
9. Easy to install and inspect.
10. Placed in most favourable zone for high and uniform superheat.
11. Designed by superheater experts to meet specific requirements.
12. 'M.L.S.' denotes the standard of quality apparatus made by Europe's largest manufacturers of superheaters.

(*See Editorial pages* 1681 *and* 1683.)

The John Thompson Patent Sectional Superheater.

(*John Thompson (Wolverhampton) Ltd., Wolverhampton.*)

This superheater (fig. 52A, p. 1682) consists of a pair of mild steel cylindrical headers connected by two groups of U or W tubes. The tubes have tapered ends machined to gauge and fitted into milled holes in the headers, making a metal-to-metal joint, and are held in position by a right- and left-hand screw stud. The advantages of this method of fixing the tubes are, perfect interchangeability and speed and ease with which any tube can be removed or replaced for any purpose, as every tube can be taken out without disturbing the headers, pipe connections, or brickwork.

The steam passes through the hot gases four times, consequently the velocity of the steam is increased and great efficiency obtained.

This superheater is adaptable to all land boilers, and is suitable for the highest pressures.

The 'M.L.S.' Superheater.

(*The Superheater Company, Limited, London and Manchester; 'Schmidt' and 'Robinson' Superheater Patents.*)

The superheater, fig. 52, consists of solid drawn steel tubular headers, to which the elements are attached. These headers are reinforced internally with special strengthening bars into which the studs for the element connections are secured. The superheater elements are manufactured

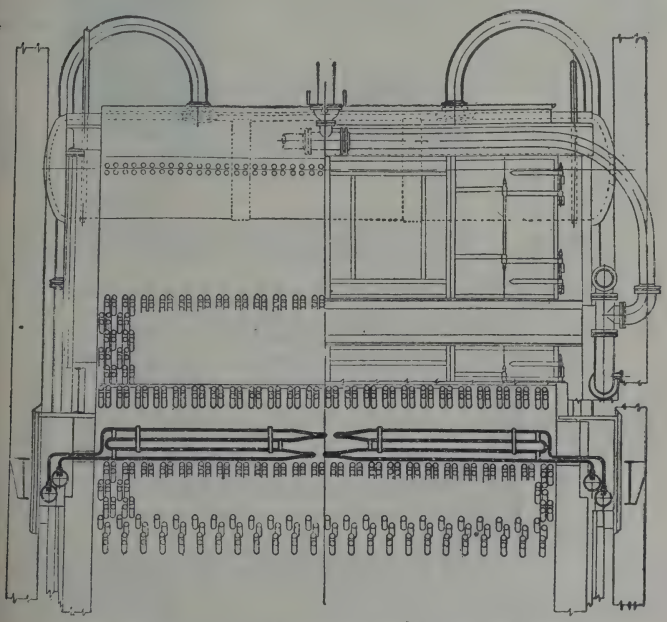

FIG. 52.—'M.L.S.' High Degree Superheater (*Inter-Deck Design*).

from high quality solid cold-drawn steel tubing, and they are connected to the headers by means of ball joint attachments, which latter have been adopted as standard by the manufacturers for their various types of superheaters. [*Continued on page* 1683.

THE 'M.L.S.' SUPERHEATER—*cont.*

The balls formed on the element inlet and outlet ends are forged integrally with the tubing itself and seat in cone recesses in the headers, so that metal-to-metal joints are provided without any form of auxiliary packing. One of the particular features and advantages of these types of superheaters is in the construction of the return bend of the element tubing. These also are machine forged from the element tubing itself, so that the final result is a return bend occupying minimum space but absolutely integral with the element tubing, and no oxy-acetylene or other form of welding is employed. By this method of manufacture, instead of there being a stress or weakening of the metal at the bend, as must occur when the tubes are bent to a small radius, the material is actually reinforced and strengthened. An additional advantage of this type of construction is that it enables superheater elements to be manufactured with the necessary number of loops to give a large heating surface without occupying any more space than the ordinary type of 'U' loop tubes generally employed. This enables the superheater to be placed in the most advantageous position in the boiler to give a constant desired superheat under fluctuating loads.

De-Superheaters.

THE 'DRAYTON' DE-SUPERHEATER.

(The Drayton Regulator and Instrument Co. Ltd., West Drayton, Middlesex.

The body of this De-superheater consists of a vertical cylindrical shell, the size of which is determined by the amount of steam to be handled, its pressure, and the maximum temperature reduction required.

The superheated steam enters the shell towards the top of the body and passes down an annular space formed between the outside of the outlet pipe which extends downwards into the body from the centre of the top and the inside of the shell itself.

The de-superheating water, which should be supplied at least 15 lbs. per sq. in. in excess of the pressure of the superheated steam, passes through a fine strainer and two pressure-operated valves into the spray ring, which distributes it to the spray heads situated on the inside of the shell. A by-pass taken from between the two pressure operated valves enables the de-superheater to be placed under hand control.

Passing through the spray heads, the de-superheating water becomes a fine mist, travelling up the de-superheater body and meeting the superheated steam in contra-flow. The mist cools the incoming steam and itself becomes steam. The mixture then passes over baffles situated in the lower portion of the shell, when it is dried, and finds its way to the entrance of the outlet tube, Grit and other solid impurities are retained by the mud stool fixed to the bottom of the body and the clean, dried, de-superheated steam rises up the outlet tube, past the thermostat of the 'Drayton All-Metal Regulator' and into the service mains.

The pressure chamber of the first pressure-operated valve is connected to the inlet branch of the De-superheater. As the valve is opened by pressure, it is impossible for water to pass to the sprays unless steam is passing into the De-superheaters. On the other hand, the opening of the steam admission valve to the De-superheater automatically opens the water admission so that no superheated steam can pass out of the De-superheater. The second pressure-operated valve is under the control of the 'Drayton All-Metal Regulator' in the outflow from the De-superheater. The 'Drayton All-Metal Automatic Temperature Regulator' is of the relay type and operates as follows: Water or air at a pressure of 15–20 lbs. per sq. in. is brought to the thermostat head through a needle valve and strainer. This relay medium has free passage through the head to the pressure chamber of the controlled valve, where it compresses a metal bellows and holds the valve open. With increasing temperature the metal tube of which the thermostat consists expands, and at a predetermined point this expansion is caused to open a small relief valve to the passage through which the relay medium passes. The opening of the relief valve causes a dissipation of the pressure in the pressure chamber of the controlled valve, which moves towards a close position. By this means the amount of water passing to the spray heads is controlled by the temperature of the de-superheated steam passing into the service mains, and adjustments necessitated by fluctuation in load are made immediately.

By means of a simple device in the regulator head, it is possible to set the thermostat to operate at any desired temperature. When these fluctuations are very rapid and when the de-superheated steam is to be kept within fine limits, the 'Drayton All-Metal Regulator' is replaced by the 'Drayton Steady.' This Regulator operates on the relay principle and is fitted with a self-check action which positively prevents hunting.

An alarm signal is provided in case the temperature rises too high through failure of the water supply.

Every De-superheater is equipped with all necessary accessories such as safety valve, pressure gauge, dial thermometer, water level gauge and steam trap of latest and most suitable type.

SCALE IN BOILERS.

A coating of scale on boiler plates somewhat increases the resistance to heat transmission from flue gases to water. The resistance on the water side of plates, however, is only a small part of the total resistance, and even if it be multiplied several times by the presence of scale, the effect on the total resistance is small, and the efficiency of the boiler is only slightly reduced.

It is not its effect upon efficiency which renders scale objectionable, but its effect in altering the distribution of the temperature gradients from gas to water through the metal and the scale. It leads to an increase in the metal temperature which may reach a dangerous amount.

The oft-repeated statement that $\frac{1}{16}$ in. of scale requires the expenditure of 16 per cent. more fuel, and that greater thicknesses require enormously increased fuel expenditure, is quite wrong.

In regard to the increase in temperature of the plates as scale accumulates, all authorities are in agreement, and practical experience confirms the fact. Stromeyer states that with clean plates the plate temperature is only 400° F., with a water temperature of 380°, when the usual quantities of heat per sq. ft. of heating surfaces are being transmitted. With $\frac{1}{8}$ in. of scale he states that the temperature of the plate may go up to 700° F., which, of course, may result in strains being set up which are highly dangerous. Especially is this so if deposits of oil in addition to scale are allowed to accumulate on the water side of the tube, and even a very thin coating of grease may result in the boiler furnace being brought down.

Actual experience with Lancashire boilers in industrial concerns confirms the statement made by Stromeyer that, taking the boiler and economiser as a whole, the drop in efficiency will not be more than 5 per cent. with an average accumulation of $\frac{1}{8}$ in. thickness of scale. It will be found also that as the boiler becomes more scaled the outlet water from the economiser will increase in temperature, showing that this portion of the plant is absorbing the heat rejected by the unclean boiler surfaces.

The thickness to which scale may be allowed to form before being cleaned off depends on the rate of heat transmission. At higher rates cleaning must be more frequent for two reasons:

(1) Because with a given thickness of scale the temperature of the metal is higher, and hence safety is reduced;

(2) Because the scale forms more rapidly. Some engineers favour low rates of transmission in order to save the expense of frequent cleaning.

Scale is prevented by suitable treatment of the feed water. See p. 1685.

Preventives of Corrosion.

Internal corrosion is due to acids in the water, or acids formed from the salts in the water, or to electrolysis.

The methods used for prevention are suitable treatment of the feed water (see p. 1685), or means for ensuring that instead of the boiler plates being attacked the corrosion is limited to renewable zinc plates placed in the boiler for the purpose.

For boilers containing sea water, it is helpful to place rolled zinc plates in good metallic connection with the inside of boiler, under water, so that no part of the boiler is more than about 6 ft. from zinc, and renew them when wasted.

In the case of large boilers at high rates of evaporation, corrosion due to oxygen dissolved in the feed-water has become troublesome. To prevent corrosion due to this cause, appliances for 'de-gassing' or de-aerating the feed-water have been introduced. (See p. 1698.)

When the boiler is not at work, corrosion can be effectively prevented by filling quite full (to the top of a small filling pipe if necessary) with water in which soda (about 50 lbs. of common soda to 100 cu. ft. of water) has been dissolved. A bright nail should be placed in sample to note if it rusts. No more soda need be used than will make the water alkaline. (See p. 1687.)

In order to prevent external corrosion, the outsides of boilers should be well painted and lagged as a protection from moisture. Ashes should never be cooled in the ashpits.

The Cumberland Electrolytic Process for Preventing Scale and Corrosion.

In the process an electric current is passed from anodes placed in the boilers to the heating surfaces.

This process, whilst primarily intended for the prevention of corrosion, when applied to boilers not only arrests corrosion, but, owing to the mechanical action of the hydrogen given off from the negative surface, will loosen scale and precipitate it in the form of sludge, which is easily washed or blown out.

Where only the question of corrosion has to be dealt with in boilers, it is found that considerably ess current is required than 1 amp. per 300 sq. ft.

One of H.M. cruisers having twelve Yarrow water-tube boilers, with a total heating surface of 9,500 sq. ft., or 4,125 sq. ft. per boiler, was fitted with the process, and it was found in actual practice that all corrosion was arrested and heating surfaces kept clear of scale by using about 1 amp: for 800 sq. ft. of heating surface. The anodes in these boilers consisted of two 7-ft.

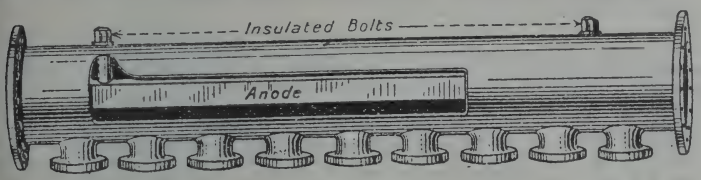

FIG. 53.

lengths of 3 in. × ⅝ in. bar iron, fitted in the steam drums of each slightly below the water level, and their life, it is estimated, will be considerably more than two years.

Fig. 53 shows the type of anode as fitted to economiser tubes. In economisers of the Green, Lowcock, or Clay Cross type it is necessary to replace the usual 4-in. pipes with others of 8 ins. diameter, otherwise the process cannot be installed.

TREATMENT OF FEED-WATER.

In steam plants using surface condensers the bulk of the water pumped into the boilers is condensed steam and is practically free from scale-forming salts—oil must, of course, be as far as possible removed. The condensed steam has always, however, to be supplemented by additional 'make-up' feed water, and as the effect of scale-forming matter in this water, even though it be a small proportion of the total feed, is cumulative, the use of most waters in the 'raw' state leads to serious scaling or to corrosion in the boilers.

Water intended for boiler feeding should be carefully sampled and analysed, and the treatment, if any, to be adopted decided upon only after careful consideration of the character of the water as revealed by the analysis.

The choice of a suitable process of treatment or softening depends on the nature and the amount of the salts found in the water.

The majority of waters available for use in industry contain salts of calcium, magnesium, and sodium, also silica in small quantities, and sometimes iron compounds. Moorland waters often contain organic acids; these must be neutralised in order that the water may be used with safety.

The salts which occur to the greatest extent are the bicarbonates of calcium (carbonate of lime) and of magnesium, and the sulphates, chlorides, and nitrates of calcium, magnesium, and sodium. These compounds are the causes of 'hardness' and of deposits of scale in boilers if used without suitable treatment.

If water containing bicarbonates of lime and/or of magnesia—$CaH_2(CO_3)_2$ and $MgH_2(CO_3)_2$ respectively—is boiled, CO_2 is driven off and the resulting carbonates $CaCO_3$, $MgCO_3$ are precipitated almost wholly in the case of the $CaCO_3$, which is nearly quite insoluble, but only partially in the case of $MgCO_3$, which is slightly soluble. Hardness due to those salts which can be removed by boiling is termed 'temporary hardness,' though it must be remembered that not *all* the hardness due to magnesium bicarbonate is temporary.

It is the driving off of CO_2 from 'temporarily hard' water as it becomes heated which cause such waters, if untreated, to deposit scale copiously in economisers, feed heaters, feed pipes, or round about the feed inlets to boilers.

'Permanent hardness' is not removed by boiling. It is due to sulphates, chlorides, and nitrates of calcium and magnesium. These salts are often more objectionable in boilers than the carbonates due to 'temporary' hardness.

The hardness of water is often expressed in 'degrees of hardness.' One degree of hardness is that due to the presence of one grain of calcium carbonate ($CaCO_3$) per gallon, hardness due to other salts being expressed as the equivalent of that due to $CaCO_3$. This is equivalent to 1 part of $CaCO_3$ in 70,000 parts of water by weight. Recently the system of expressing hardness in 'parts $CaCO_3$ per 100,000' has been advocated and is sometimes used. Care is therefore necessary in stating hardness, to make clear which system is used.

Hardness may be measured by finding the amount of a standard soap solution required in order to produce a permanent lather with a definite quantity of water. This method does not distinguish between the temporary and the permanent hardness, and is now being superseded by tests for alkalinity by means of a standard acid, the test being made in two stages giving the amounts of both kinds of hardness.

Analysis of the water by a chemist is always advisable, as it is only by ascertaining the particular salts causing hardness that the proper kind and proportions of reagents necessary for its treatment can be determined with accuracy.

Artesian waters from sand rocks are usually soft, those from limestone rocks or the red marls are hard. Superficial gravels often give hard waters, and the clay rocks, such as the lias, are often productive of hard water. Coal measures often give very bad water, even from sandy strata. Ancient rocks such as granite yield soft supplies, and the moorlands of the north country, being chiefly of millstone grit, yield remarkably soft water. Chalk yields hard water, but where covered with London clay the hardness is very much reduced, often falling to 6 degrees.

The reagent generally used for removing 'temporary' hardness is lime, in the forms of slaked lime, quicklime, or lime water. If the 'temporary' hardness is due to magnesium bicarbonate the amount of lime—i.e. hydrated lime, $Ca(OH)_2$—required is twice what would be necessary if the hardness were due to calcium bicarbonate.

Permanent hardness can be removed by the use of soda ash (carbonate of soda) for calcium salts, or by soda ash together with lime for magnesium salts.

Thus the lime-soda treatment serves to deal with waters containing a variety of salts, causing both kinds of hardness.

The proper quantities of the reagents to be used can only be correctly determined by reference to the results of the analysis of the raw water. The correctness of the treatment should be checked from time to time by applying simple tests to the treated water.

Caustic soda reacts with bicarbonate of lime, $CaCO_3$ being precipitated and sodium carbonate remaining in solution. If sulphate of lime is present, the sodium carbonate will react with it, calcium carbonate being precipitated and sodium sulphate then remaining in solution. Unless the two salts of lime are present in particular proportions the sodium carbonate formed in the first reaction will not be correct for the second, and as a rule additional sodium carbonate must be added. The caustic soda and the caustic soda and soda ash processes are based on these reactions. These processes are, as a rule, more expensive than the lime-soda treatment, and are, in any case, not so widely suitable; there are, however, certain waters for which these processes are suitable and efficient.

In general, it is better to treat the feed water before it enters the boilers rather than to use 'boiler compounds'; and, obviously, efficient filtering in order to remove the muddy deposit or substances precipitated in the feed tanks or softening plant, is essential.

Filters are charged variously with sponge, wood wool, cloths, crushed quartz, sand, broken coke, or sawdust, suitably packed.

With regard both to prevention of scale and prevention of corrosion, it is of great importance that an analysis be made and each case treated separately, so that the proper treatment may be determined.

Not only is mere analysis of the water required, but the treatment to be adopted should be decided upon with reference to the actual behaviour of similar waters under the conditions of steam generation.

Many of the substances used in boilers with the intention of preventing scale or of keeping scale in a loose, easily removed form are of little value, and occasionally, particularly if introduced in solid form, may themselves be a source of danger.

That in some cases a properly chosen compound for use in the boiler itself may be justified has been shown by E. M. Partridge (see *Power*, July 8, 1924). Scale formation depends on whether the insoluble matter formed in the boiler will attach itself to the plates, etc. Colloidal chemistry shows that the addition of certain colloidal substances to the water reduces the tendency of small suspended particles to coalesce, so that the insoluble matter forms a sludge rather than a scale. Partridge points out that the presence of this sludge in the boiler may be less objectionable than the increasing concentration of soluble sodium salts resulting from ordinary softening.

Boiler compounds, however, should not be used unless by the advice of a competent expert.

In connection with the application of colloidal chemistry to the treatment of feed water, it may be remarked that in a softening plant, the soda renders part of the chalk colloidal against which filtering is ineffective. The heat of the economisers or boilers changes the chalk from its colloidal form into an ordinary deposit, resulting in scale. 'By the use of suitable colloids, however, the insoluble matter resulting from lime and soda treatment is prevented from interlocking to form scale. Residual hardness, generally present to some extent in a water treated through a softener, also comes under the beneficial control of the colloids, because as this residual hardness is rendered insoluble by elevated temperatures, it is enveloped by the colloid, and so prevented from interlocking to form scale.' (*W. H. Bannister*, '*Institute of Mining Engineers*,' April 26, 1924.)

Aluminium sulphate or alumino-ferric may be used in small quantities to produce the colloid ffect, the precipitate being flocculent, so hastening settlement and facilitating removal.

It should be borne in mind that after treatment in a softener, water still contains salts, though hey are then soluble ones, and that undue concentration of these in a boiler is harmful, leading to oaming.

A. Winstanley (*Water and Water Engineering*, February 20, 1924) recommends that where eed water containing salts of sodium is used, samples be drawn from the boiler at intervals o determine the degree of concentration. From these samples the safe period of running so far as salts in solution are concerned) may be fixed. He suggests that 0·4 lb. per gallon e the maximum concentration allowed. He also recommends that the analysis of the feed vater be used to compute the amount of matter which will be precipitated in the boiler, and so .etermine the maximum period of continuous running so far as salts precipitated are concerned. As a fairly safe rule, he would fix a maximum of ½ lb. per sq. ft. of interior surface for adhesive alts, and double that amount for sludge or non-scale-forming material.

It is customary not to soften feed water completely, but to reduce the hardness to three or our degrees. With certain waters, however, containing acid-forming salts, such as magnesium hloride, it is advisable to use sufficient reagent to soften completely and to leave a small surplus, o that the treated water is slightly alkaline; otherwise corrosion occurs.

Dr. Joseph G. Rogers has proposed two methods of preventing boiler incrustation. One consists of introducing into the boiler a sufficient quantity of *sodium oxalate*, which converts the calc-forming impurities of the feed-water into insoluble oxalates as soon as they enter the boiler. These oxalates are precipitated as a mushy sediment, which has no tendency to form scale, and which may be blown out from the mud drum from time to time. The other consists in the use of *sodium tannate*, which is kept constantly present in the boiler in solution. It decomposes the calcium and magnesium carbonates as they enter, tannates being precipitated in a light, flocculent, amorphous form, which gradually accumulate in the mud drum, from which they may be readily blown out from time to time. The sodium carbonate formed in the reaction remains in solution, becoming bicarbonate by appropriation of the free carbonic acid in the water. This reacts upon the calcium sulphate, forming sodium sulphate and calcium carbonate, which latter in turn is acted on as above by fresh portions of the sodium tannate. The constant presence of the alkali protects the iron from any injurious action of the tannic acid. A similar reaction will take place between the tannate and the already-formed scale, though the action will be a gradual one.

'Caustic Soda in Boilers.

Failures of boiler plates due to 'embrittlement' have recently been investigated, and it is stated that the evidence points to concentration of caustic soda or of carbonate of soda in minute cracks on the surface of the plates in the vicinity of rivets as being the source of the trouble. It is the association of the soda compound and stress that appears to lead to a dangerous condition.

The degree of concentration which may lead to 'embrittlement' is not yet established, and, indeed, whether the presence of the soda is the true explanation of embrittlement at all is controversial. In view of the possible risk, however, it is advisable that when caustic soda has been used to assist in the removal of scale or for the prevention of corrosion when a boiler is out of service, it should be thoroughly washed out before the boiler is again put to work; also the concentration of caustic soda or of carbonate of soda due to softening reagents should not be allowed to become sufficient to give pronounced alkalinity.

The 'Dionic' Method of Water Testing.

(Evershed & Vignoles, Ltd.)

This method (Digby & Bigg's patent) is based on the fact that the electrical conductivity of water varies with the degree of hardness, or impurity in solution.

The essential units of the apparatus are a glass tube containing the water under test, together with a hand-driven direct-current dynamo and a conductivity meter.

A current is passed between electrodes, which are sealed at a fixed distance apart in the tube, whilst automatic compensation for temperature is effected by an adjustable thermometer which varies the effective cross-sectional area of the liquid path.

A direct reading of the conductivity is obtained, which affords information as to :—

(*a*) Whether condensers are leaking, and the extent of the leakage.
(*b*) The presence and degree of priming, if any.
(*c*) The control of oil-eliminating and water-softening plants.
(*d*) Feed-water.

A recording instrument of this type is now available.

The Crockatt Simplex Patent Electric Salinometer.

(W. Crockatt & Sons, Ltd., Glasgow.)

This is a direct reading instrument showing the amount of salt or other impurity in water, in grains per gallon, or other convenient measurement. An instrument board (fig. 53A) is fitted on

the control platform, and has on it the indicating instrument, warning lamp and relay for each point to be tested, interlocking switches and a warning bell or buzzer.

The lighting supply is coupled to a master switch on the board, and leads are run to the compensator boxes (fig. 53B) which contains the detector cell and compensating thermometer. One of these boxes is fitted for each condenser or feed line in which it is desired to measure the impurity.

A continuous stream of water flows through the thermometer pocket and the cell, and automatic correction is made here for varying temperature of the water.

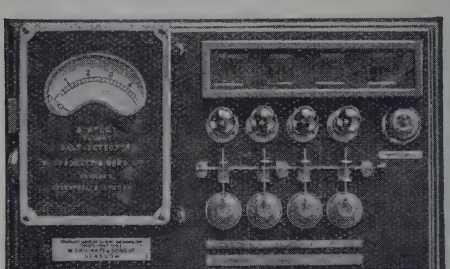

FIG. 53A.

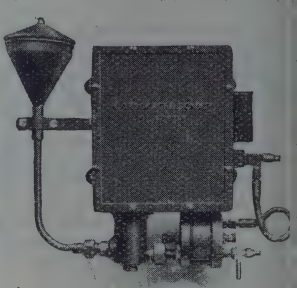

FIG. 53B.

The cells are, normally, all in circuit through the warning lamps, and the glow of any one of these indicates the presence of salt. This can immediately be measured by switching over that circuit to the indicating instrument. The switches for this purpose are all interlocked so that only one cell can be switched into circuit with the instrument at a time, the others being all in circuit through the lamps.

In the event of a large influx of salt or other impurity at any point, the corresponding relay closes, and a bell or buzzer gives audible warning to the engineer.

The Admiralty pattern instrument is entirely self-contained, the water being led directly to the thermometer pocket and cell, which are attached to the instrument case. This pattern indicates from zero (pure distilled water) to ·5 grains of chlorine per gallon, on a scale measuring over 4 ins. long, but the calibration and the range can be made to suit the special conditions of each case.

BOILERINE.

(*Boilerine Ltd.*, 885A-897 *Old Kent Road, London, S.E.* 15.)

This is a viscous fluid, consisting chiefly of a carbon compound which has no action upon iron, steel, or other metals, but which has the property of rendering all water impurities innocuous and incapable of forming scale, while it also works its way through the interstices of the scale, the rate of this percolation depending on the porosity and degree of compactness of the same, and when the preparation reaches the underlying plate of the boiler it there diffuses and insinuates itself behind the incrustation, causing it to crumble and flake, so that when the boiler is opened it can readily be removed. The preparation as a preventive of scale differs from the old style of boiler composition, inasmuch as it absorbs the gaseous carbonic anhydride from the water, forming an intermediate salt which throws the scale-forming salts out of solution, suspending them in the water in a non-crystallisable and powdery state. Incrustation is thus prevented. Steam generated from sea water containing 'Boilerine' is free from ammonia. Boilerine is not only a preventive, but also a disuniter of incrustation in boilers; it is absolutely non-volatile, and does not affect the purity of the steam produced from water treated with it; it does not discolour the water in the boiler, and it will not cause priming. It is guaranteed free from arsenic, acids, and poisonous substances, and is a neutraliser of grease and acids.

The boilers should be blown down and treated with Boilerine *daily*, as by this system greater efficiency is obtained. With average feed-waters the cleaning out should be done at intervals not exceeding 150 to 300 hours for vertical and locotype boilers; 500 hours for water-tube and marine dry-back boilers; 300 hours for the two bottom rows of tubes of Babcock boilers; 1,000 hours for Lancashire, Galloway, and Cornish boilers.

'FOLIAC' BOILER GRAPHITE.

(*Graphite Products Ltd.*)

The use of this material enables scale in a boiler to be easily and safely removed, a wire brush being used for the purpose. The graphite does not attack the metal of the boiler, nor, it is claimed, does it cause the metal to be attacked; it is not affected by any acid in the water or by the heat generated in the boiler. Particles of the graphite work through the minute fissures existing

in the old scale and gradually penetrate between the scale and the metal. The scale thus loosened may be rapped off or removed with regular cleaning tools with little trouble. If the scale is very hard and thick it may require as long as three or four months for graphite to loosen it, but once removed the scale can never again adhere firmly to the metal as long as the graphite treatment is continued. The graphite also becomes thoroughly intermixed with new scale as it forms, rendering it soft and friable.

The graphite is introduced in the form of fine powder with the boiler feed, about half a pound being used per day for a 250-h.p. boiler.

Feed-Water Softening.

The two principal methods of feed-water treatment are (1) by lime and soda ash (see p. 1686) and (2) by zeolite, or base exchange materials.

The zeolite method consists in the use of special sodium aluminium silicates placed so as to form a bed three or four feet deep in a cylinder, and passing the hard water through this bed, when it runs out with absolutely zero hardness.

The soluble calcium and magnesium salts of every description interchange with the sodium of the zeolite, the calcium and magnesium salts remain in the tank and their equivalent in sodium sulphate and sodium bicarbonate is in the softened water.

The zeolite is 'revived' by blowing strong salt solution through the bed. The sodium zeolite is re-formed and the calcium and magnesium chlorides are run to waste. The plant will run for about eight hours, and then is 'revived' for half an hour.

The ideal method of softening is to reduce to 6 or 7 degrees of hardness by the lime-soda process and then to finish by zeolite, obtaining absolutely soft water with only a small amount of sodium bicarbonate. (Brownlie, in *World Power*, May 1927.)

Water Softening Plant.

WATER SOFTENING BY MEANS OF ZEOLYTIC EXCHANGE PROCESS.

(*'Permutit' Process—United Water Softeners, Ltd.*)

The Permutit system comprises filtration through a bed of the granular base-exchange material termed 'Permutit,' which has the property of giving up its sodium base to any water which is passed through it in exchange for any calcium or magnesium contained in the water.

This action takes place irrespective of whether the calcium or magnesium in the water is in the form of carbonate or sulphate, i.e. quite independent of whether the hardness is temporary or permanent.

There are two varieties of Permutit, the synthetic or artificial (Permutit A) and the treated and standardised natural product (Permutit B). Both are rapid in softening and regeneration, but Permutit B is more rapid in its action in either direction than any other base exchange material, either natural or artificial.

Such a method affords a means of presenting to the hard water a large supply of the softening element in readiness to be drawn upon by the water itself in exact proportion to its quantity and hardness; in other words, Permutit contains, in large excess, the active softening element, which, however, is effective in precisely the degree required to completely effect the softening of the water, and no more.

This action continues for so long as there remains in the Permutit active material (sodium) available for exchange; the total softening capacity of Permutit being represented by the multiple of the hardness and the quantity of any water, so soon as this quantity of water of the specified hardness has passed through the bed of Permutit, the sodium will become replaced by calcium or magnesium (or both), extracted from the water; thereafter, no further effect takes place either in respect of the Permutit, or of any further water passed through it. A fresh charge of the sodium is then transferred to the Permutit by flowing through it a weak solution of common salt (NaCl), when a similar exchange action takes place.

In this stage revivifying, or in its technical term 'regeneration,' takes place, by an exactly similar process. The bases of the hard salts (calcium or magnesium) are replaced in the Permutit by the sodium contained in the salt solution; and the calcium and magnesium combine with the chlorine of the salt forming the chlorides of these bases, which as a clear liquor may be run into any drain. Any slight excess of salt solution remaining amongst the granular particles of the Permutit after complete regeneration has been effected is washed out by a short rinse with clean water.

Permutit A can be regenerated in about one hour, while Permutit B is capable of being completely regenerated in 15 minutes. This rapidity of regeneration makes it practicable to use one unit practically continuously throughout the twenty-four hours.

A complete cycle of operations has then been completed, when hard water can again be passed through the filter, softening being complete as before, and continuing until the maximum quantity for which the filter is designed has again been treated.

During this to-and-fro softening action, the Permutit itself suffers no damage or wastage, it being merely a vehicle for the zeolytic exchange action which is the peculiar property of the substance. There is, therefore, afforded an extremely simple, though entirely scientific means for completely softening water of any hardness without any deposit of solid matter; any necessity for settlement and subsequent sludging away of precipitates, as was the case in the previous lime and soda systems, is thus completely obviated.

Kennicott Water Softener Co. Ltd.

IMPERIAL HOUSE, KINGSWAY——LONDON, W.C. 2.

LARGEST MANUFACTURERS OF WATER SOFTENING PLANT IN THE WORLD.

Another important feature attaching to the 'Permutit' system is the valuable means which it affords for treating water as it passes through the mains under pressure; and it has thereby become possible to treat any supply for industrial or domestic purposes as it enters the building in which it will be used, and to deliver the same in a completely softened condition to storage tanks in the top of the building, without any break in the pressure or consequent necessity for repumping.

Absolute uniformity in the final water, as well as elimination of any necessity for skilled control of the treatment by a chemist, are also features of importance attaching to the Permutit system.

In cases where temporary hardness preponderates heavily, and the difference in cost of lime and salt is also in favour of the lime treatment, a Permutit filter may with advantage be arranged to supplement a preliminary lime treatment.

Elimination of Iron and Manganese from Water Supplies.

By means of a special type of Permutit, prepared and oxidised by the use of manganese salts and permanganate, all traces of iron and manganese can be eradicated from a water supply, the treatment being effected under pressure and without calling for any extra pumping.

Large installations for some of the leading public water supplies throughout Europe have been laid down with conspicuous success for this purpose, as well as for the softening of the water as above described

The Permutit system constitutes practically the only one of certainty and success for the removal of manganese.

General Design of Permutit Plant.

The type of plant utilised for effecting Permutit treatment of water is of a standard design and is shown by fig. 54.

A mild steel cylinder of such proportions as are requisite, accommodates the proper quantity of Permutit.

Provision is made by means of suitable pipe connections and valves for agitating the Permutit bed by means of a flow in the opposite direction to that of filtration. By this means any uneven action due to air pockets or channels in the bed of the Permutit is prevented.

In the case of single units, the filter carries above it a shallow tank for dissolving the salt for regeneration—which is usually arranged to be effected once in each day.

In the case, however, of multiple-unit plants, these overhead salt tanks are dispensed with; and a common tank in steel or ferro-concrete provided, in which the salt solution is made up for the entire battery of the filters.

A complete plant of this description is in operation for both iron removal and softening at the Hooton Pumping Station of the West Cheshire Water Company.

Plants upon similar lines have been installed by a very large number of the leading industrial concerns both in England and on the Continent, as also by the Municipalities of Breslau, Dresden, and other leading cities.

The Kennicott Type 'K' Water Softener.

(*Kennicott Water Softener Co., Ltd., Imperial House, Kingsway, London, W.C.* 2.)

The Kennicott Type 'K' Plant is so designed as to be very simple to operate, and at the same time extremely accurate. The plant is absolutely positive in its action, and there are no oscillating parts to get out of order, and no valves or cups to get made up with lime. Fig. 55 (p. 1692) shows the general construction of the plant, the action of which is as follows:—

The calculated quantity of chemicals required for a day's supply are run into the chemical tank B, which is filled to a definite level. The hard water enters the plant by way of the pipe E into the hard-water box F, whence it flows through an adjustable slot over the water wheel D and out of the chute G at the bottom of the water wheel casing into the top of the downtake H. The incoming water, passing over a water wheel, provides all the power required for operating the plant. It drives the main shaft, and this shaft drives two vertical shafts, one in the downtake and the other in the chemical tank B. The shaft in the chemical tank B has a 4-bladed agitator at the bottom, and this keeps the chemicals constantly and homogeneously mixed. The shaft in the downtake has an agitator fixed to it, and this ensures that the chemicals added are thoroughly mixed with the water, a most essential feature. In order to proportion the chemicals, a small quantity of hard water from the hard-water box F is by-passed to the dividing box I, where the small quantity of by-passed water is divided, a portion running into the regulating tank K, and the rest down the drain. The dividing box is set so that the amount of water run into the tank K fills up this tank in a definite number of hours, generally sufficient for a day's run, and as this tank fills, the float riding on the water in this tank gradually rises and at the same time lowers the weir L in the chemical tank B, the float in the tank K being connected with the weir in the tank B by means of a flexible cable passing over two pulleys. It will thus be seen that the chemicals are added in an absolutely definite proportion to the quantity of water entering the plant. Immediately the chemicals come into contact with the water, the whole is thoroughly mixed by means of the mechanical agitator in the downtake, and the water passes down to the bottom of the downtake H, and finally flows upwards in the direction of the arrows, at a very slow rate, and is finally filtered at the top of the plant.

KENNICOTT TYPE 'K' WATER SOFTENER.

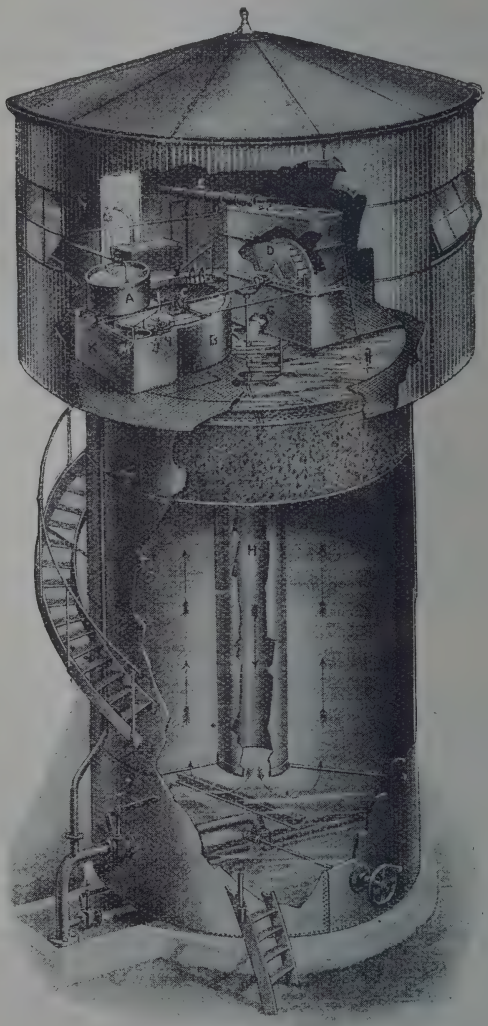

FIG. 55.

Any mud contained in the water, and the bulk of the precipitated hardening salts, settle on the bottom, and it is very necessary that this sludge should not be allowed to accumulate, otherwise the moving water will very quickly wash it up into the filter. By means of the *Kennicott Patent Revolving Sludging Gear*, however, the whole of the sludge settled on the bottom can be removed, the action of the sludging gear being very similar to a vacuum cleaner.

No Kennicott plant is made with less than three hours' settling, this being the minimum time that should be allowed for the complete precipitation of the hardening salts. With all Kennicott plants the mixing tank A is supplied. This tank is sufficiently large to hold a full day's supply of chemicals, so there is always a charge in readiness when the proportioning tank B is empty.

As the main tank always stands full of water, the clear soft treated water discharges from the overflow at the side of the main tank at a point above the filter as fast as the water to be treated enters the top of the downtake 'H.'

The machine is continuous and wholly automatic in its operation. The flow of the water furnishes all the power necessary for mixing the chemical reagents with the water and for operating the mechanism.

Every installation is designed for the work it has to perform, and to suit the site it must occupy. The chamber can be made either cylindrical or rectangular in shape. When a supply of exhaust steam is available, great economy can be obtained by installing a Kennicott Patent Type 'K' combined Heater and Softener.

The operation of this type of plant is exactly similar to the Kennicott Cold Water Softener described above. In addition to the chemical proportioning gear, there is fitted a very substantial heater, fitted with removable trays, over which the water passes. Steam is admitted at the bottom of this heater after passing through an oil separator, and passes upwards through the water. This raises it to boiling point, a considerable proportion of the hardening salts being at the same time deposited in the trays, which are from time to time removed for cleaning purposes. Practically the whole of the hardness originally present in the water is by this system removed, and at the same time a soft feed water of high temperature is available for boiler purposes.

Plants of the latest Type 'K' design of all sizes from 500 to 150,000 gallons per hour capacity are actually in operation.

The Kennicott Water Softener Co. also manufacture a Zeolite Water Softener which will reduce water, irrespective of its initial hardness, to zero degrees. This softener works under pressure, and the zeolite employed is a natural mineral which has been used for over ten years without showing any appreciable sign of deterioration.

The Kennicott Water Softener Co. claim that this zeolite is the most efficient and most durable zeolite procurable.

The Royles Automatic Water Softener and Purifier.

(*Reisert System.*)

In this apparatus, fig. 56, p. 1694 (*Royles, Ltd., Irlam, near Manchester*), the bicarbonate of lime is precipitated by hydrate of lime (lime water), and the sulphate of lime by soda. The softened water is then filtered and discharged.

The apparatus, which acts entirely automatically, consists essentially of an automatic lime saturator and decanter B, a soda chamber D, a water-distributing tank E with a lime-slaking division A and soda-mixing division C, a reaction chamber F, and an automatic self-cleansing filter K.

The *Lime Saturator* B requires no stirring contrivance, and lixiviates the lime completely; and owing to its upward widening shape, it turns the saturated lime water into a clear fluid.

By a constantly uniform water supply through the micrometer valve 3 from the distributing tank E, which is conducted downwards through the central pipe O, the lime paste at the bottom is stirred up and thoroughly impregnated, and rises, at first partly with the water, until the rapidity of the rising water diminishes so much, owing to the upward widening shape of the saturator, that the undissolved lime particles are no longer able to follow, so that the saturated lime-water, clarified, then leaves the saturator B at the top, and is carried into the reaction chamber F by way of the mixing pipe E^1.

As lime possesses the property of dissolving in a definite proportion in water until the latter is saturated, it is possible to continually keep a uniform stream of saturated lime-water supplied as required, for the precipitation of bicarbonates of lime and magnesia. Upon this uniform addition of lime depends the degree of purification of the water.

In the *Soda Apparatus* D, a quantity of soda (which, unlike lime, is very soluble), one gallon of water at 60° F. dissolving up to 1¼ lb. of dry sodium carbonate that will suffice for one or more days, is dissolved in the chamber C and let down into D through cock Q.

The action of the soda apparatus is based on the fact of the soda solution having a greater specific gravity than water, and thus the water flowing from the distributing tank E through the small micrometer valve 1—which is adjusted in accordance with the amount of soda required—into the soda chamber D, remains always on the surface of the soda solution (no mixing taking place), and displaces the same, it being carried through the small pipe from the bottom upwards, and into the mixing pipe E^1, and finally into the reaction chamber F.

The water-distributing tank, E, is supplied with the hard water to be treated, by pipe and cock as shown; it is also provided with an overflow pipe.

It is further provided with three micrometer valves at an equal height, viz.—(1) for the supply to soda tank; (2) for the supply of untreated water to the reaction chamber; and (3) for the supply to the lime saturator B. By arranging these three valves at an equal height the quantities of water flowing from them are always proportionate in the event of less water being supplied to the apparatus than corresponds to the capacity; or in the event of the water supply ceasing altogether, they cease simultaneously.

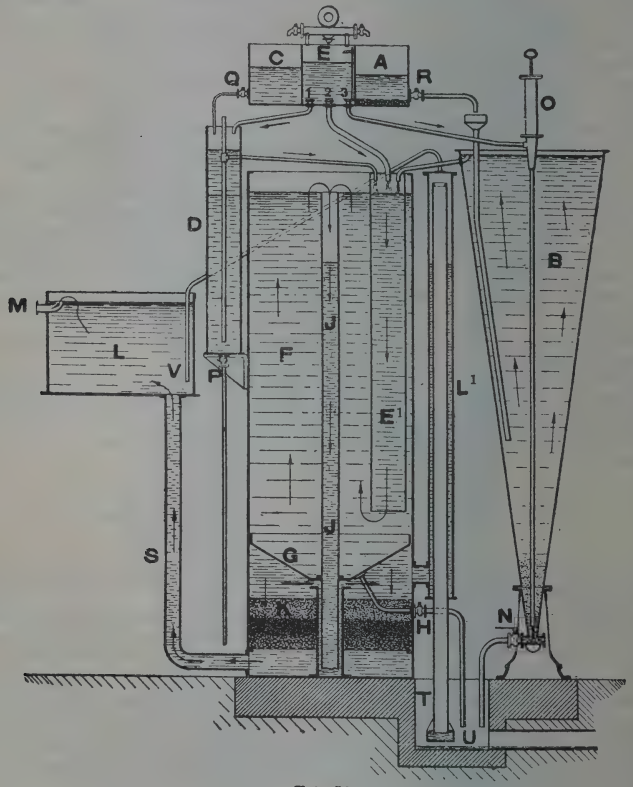

FIG. 56.

A *Lime-Slaking Division*, A, is arranged in the distributing tank. In it, once a day, the required quantity of lime is slaked by means of a supply of water obtained from the water inlet pipe. The lime paste is then conveyed in bulk to the bottom of the lime saturator, B, through the short depending pipe illustrated, by opening cock R. The *Reaction Chamber* F thus receives through the mixing pipe E¹, the untreated water, lime-water, and soda-water, which remain in this chamber until the chemical reactions have been accomplished.

The continuous inflow of the water and chemicals above described overflows *via* the pipe J into the filter chamber K, following the course of the arrows downward through the filter bed and upwards through pipe S into the tank L, the rest flowing away, at M, to reserve or for use. The height of the column of water in the pipe J will vary with the resistance of the filter bed, and as the latter fouls, the water will rise higher and higher in J.

Similarly it will rise to an equal and corresponding height in the Syphon pipe L¹, and as soon as the resistance through the filter bed reaches such a point as to cause the water to over-

flow this pipe, it forms a syphon and instantly reverses the current through the filter bed, drawing backwards the clear water held in the small tank L, thus thoroughly and automatically cleansing the filter, the sediment being discharged at T into the gully U. The small tank L is proportioned to hold sufficient water to thoroughly flush the filter K, and as soon as the tank is empty air enters *via* the pipe V, and destroys the syphonic action.

The filter then resumes its normal working, and so continues until the fouling is again such as to cause the pipe L to overflow, when the cleansing action is repeated. The loss of water in reflushing is very trivial. The filtering material rarely requires renewal.

The Lassen-Hjort Water Softening and Purifying Plant.

(United Water Softeners Ltd.)

The outstanding feature of the Lassen-Hjort patent automatic water softener, figs. 57 and 58 (p. 1696), is the device it embodies for the separate and exact measurement, in small, absolutely definite, and predetermined quantities, of both hard water and softening reagents. This device

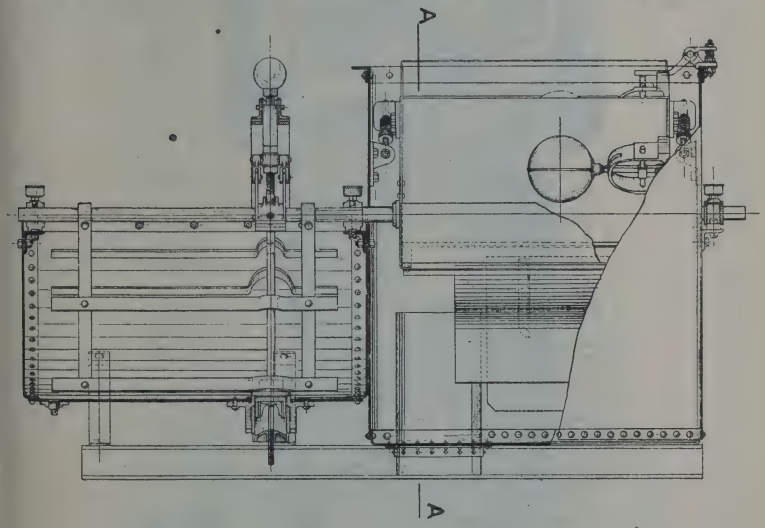

Fig. 57.

(termed the Lassen-Hjort Patent Measuring Apparatus) renders it possible to treat water or effluents of any character with any reagent or combination of reagents, in rigidly proportionate quantities, which can be varied at will and adjusted with the utmost precision.

The hard water to be softened is fed into the plant by a pipe which alternately fills each of the compartments of a two-chambered tipper oscillating on a shaft carried in bearings. When one of these compartments is full of water the disturbance of equilibrium causes the tipper to over-balance, and, by doing so, to discharge its contents of water into the tank in which it is suspended: at the same time the other compartment of the tipper is brought under the orifice of the inlet pipe and filled in its turn with hard water, to be discharged in the same manner when full. A counter affixed to the tipper shaft registers the number of oscillations, so that the quantity of hard water to be treated is thereby accurately measured.

An important feature of the apparatus is the recently introduced patent locking gear, by means of which the oscillating receiver is prevented from tipping until it contains a predetermined quantity of water. This ensures absolute precision in the measurement and delivery of the water to be softened.

The apparatus, fitted with this locking gear, has been tested as a water meter pure and simple, at the National Physical Laboratory, Teddington, and certified to be correct within 1 per cent.

At each discharge of water from the tipper into the tank in which it works, a corresponding amount of water is displaced from this tank through a standpipe and shoot into the reaction chamber of the softener, and here it receives at the same moment the requisite charge of chemical

LASSEN-HJORT WATER SOFTENER.

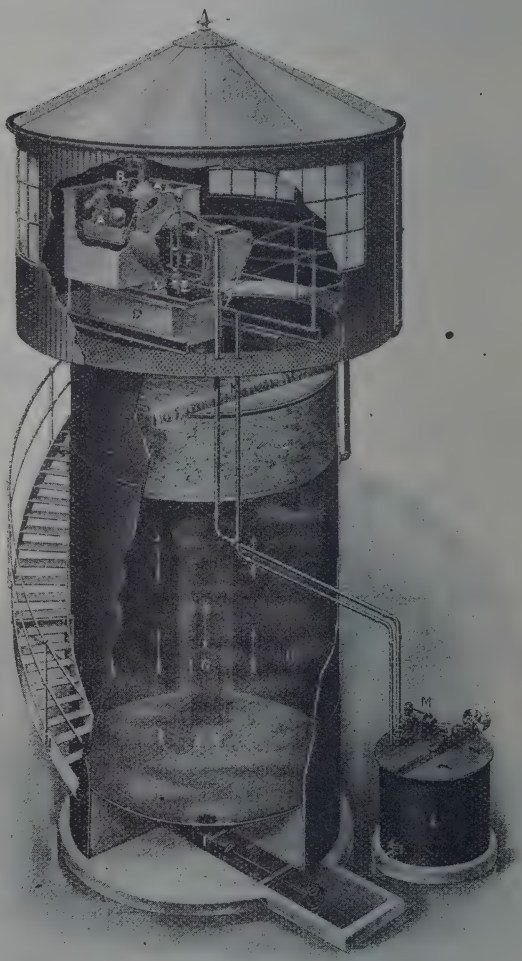

FIG. 58.

"PERMUTIT"

the Permanent

BASE-EXCHANGE SOFTENER

More rapid, both in softening and regeneration than any other base-exchange plant.

The only softener which gives zero water continuously throughout the run.

Lowest salt consumption compatible with zero water throughout run.

Can be completely regenerated, i.e. washed, salted, and reflushed inside 20 minutes.

Unaffected by Carbonic acid.

F. 1697

solution from the semicircular chemical container affixed to the side of the tipper tank. This is effected by means of a ' positive discharge valve ' (patented) placed in the bottom of the chemical container, which is opened at each movement of the tipper, and caused to deliver into the reaction chamber the exact amount of softening reagent (in the majority of cases a mixture of lime and soda ash) required to soften it to the guaranteed figure.

The valve can be adjusted (with great ease and over a wide range) to discharge any specified quantity of reagent required by the volume of water in the tipper compartment, so that the plant can be easily regulated while working without any necessity for altering the strength of the chemicals or changing the solution in the container. The precision with which the chemicals and water are measured and mixed makes for speedy completion of the reaction.

A special feature of the tipper gear is the fact that all the working parts are in sight, whilst the whole gear is simpler (it is claimed) than that of any other water softener plant in use.

The average results obtained with the Lassen-Hjort plants show a hardness of the water after treatment, of 2° Clark, while the residual alkalinity (i.e. excess of lime and soda remaining in the water after the conclusion of the softening process) averages only 1·5 grain per gallon, or one and a half parts in 70,000 parts by weight, i.e. practically no excess of alkalinity.

The plant being primarily designed for adding lime automatically to water in exactly measured quantities, is very suitable for carrying out the Houston ' excess lime ' process of water sterilisation.

The Lassen-Hjort process has been adopted by Messrs. Babcock & Wilcox, who supply it throughout the world under license from the makers.

Many thousands of Lassen-Hjort plants are at present in use.

Filtrator Process for Prevention of Scale.

The use of ' colloidal ' substances to prevent scale formation has already been referred to (p. 1686).

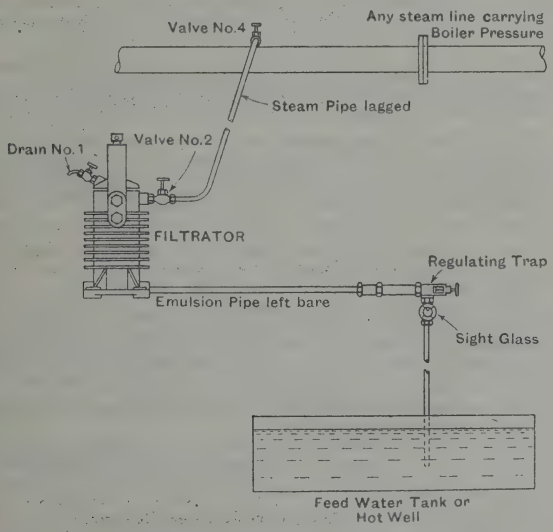

FIG. 58A.

A recently introduced patented system for carrying out such treatment is that of Messrs. Filtrators, Ltd.

The Filtrator is an apparatus having for its object the prevention of the formation of scale in steam boilers, economisers, and condensers, and the removal of scale existing previous to its application.

The apparatus (fig. 58A) is made both for air cooling and water cooling, and consists of an outer cast-iron cylinder with an inner perforated cylinder containing ordinary commercial linseed. Live steam entering the apparatus passes into the centre tube of the perforated cylinder and permeates the linseed, being induced to pass through the seed by the condensation taking place on the walls of the outer cylinder. By this means, a mucilage or emulsion possessing the properties of colloidal solutions is extracted from the linseed.

The steam is taken from any convenient steam line into the Filtrator, and the emulsion is led through a regulating trap of such a type that a constant flow of the linseed mucilage is maintained into the feed water. This mucilage, or emulsion, when leaving the Filtrator, is very little different in its consistency from ordinary water, and freely mixes with either cold or hot water in the feed tank so that the colloidal character of the solution is automatically maintained as long as the Filtrator is in operation.

A very important point about this method of installing the Filtrator is that it permits of the economisers being treated to keep them free of scale as well as any number of boilers being served from one central installation.

There are other methods of arranging the Filtrator, such as attaching direct to the boiler, but the arrangement suggested above is recommended.

It is well known that the cause of formation of scale in steam boilers consists mainly in the precipitation of different solid matters, when the water is heated to the temperatures characteristic of each, and also from the chemical reactions which take place in the water. When these matters are precipitated they adhere to the surface of the boiler and form scale, but when the mucilage from the linseed is introduced into the water in sufficient quantity it coats over all the scale-forming particles with a thin film, thereby preventing crystal growth (scale), and also preventing adhesion to the boiler shell. It must be obvious that if scale is not formed a sludge will be formed, and this requires periodically blowing down. The amount of blowing down does not exceed that required under ordinary working conditions.

Old scale will also be gradually removed. The emulsion penetrates the cracks which always exist on the surface of old scale; it thereby reaches the heated metal, when it expands, loosens the old scale, and this is gradually torn away by the circulating water.

The action of the mucilaginous emulsion is a physical one, no chemical reactions whatever taking place, so that this process is entirely harmless to the metal of the boiler and all fittings. By this physical method it is possible to treat any type of water, including sea water, and it is of great value where the water is of varying hardness or salinity.

Bare metal is not obtained with the Filtrator, but a protective scale coating which may reach, but will not exceed, 1-32 in. in thickness is formed in Lancashire or other fire tubular type boilers. In water tubular boilers, there is a maximum thickness of 1-64 in. of hard scale which forms a protective coating on the shell of the boiler, and over prolonged periods of steaming, scale is removed as soon as it reaches this maximum thickness. All scale which is formed is of a non-adhering character, and therefore the boiler metal surfaces are always open to water percolation.

One of the very interesting features of the treatment of the water in the boilers is that when marine boilers have been fitted with the apparatus, no corrosion or pitting has been found inside the boilers, notwithstanding that sea water only is used as 'make up.'

The lubricating oil that sometimes gets inside the boilers, owing to the impossibility of entirely eliminating it from the feed water by means of oil filters, has not been found in boilers fitted with Filtrator Apparatus. The most acceptable explanation is that the emulsion prevents the tiny globules of oil from agglomerating and forming film on the water's surface. It appears that the oil remains in this case in a finely divided state in suspension in the boiler water.

The Filtrator is applicable also to all types of condensers and water circulating systems generally.

As the husk of the seed remains intact throughout the process, and the condensed steam can extract only the matter soluble in water, no oil can possibly be extracted from the linseed.

Removal of Gases from Feed-Water.

The dissolved oxygen in feed-water may be reduced in amount in various ways. One method is to use a closed feed system, the condensate being kept from contact with the atmosphere, and the make-up feed-water being passed through the main condenser in which it is exposed to the vacuum and thus gives up part of its dissolved gases. Alternatively, a special de-aerating vessel may be included in the feed circuit. In the de-aerator the feed is finely divided or sprayed

by means of nozzles or by being made to fall in small streams over trays or through perforated plates. The de-aerator is either connected to the condenser or is provided with an air ejector so that the feed-water in its state of spray is exposed to a vacuum.

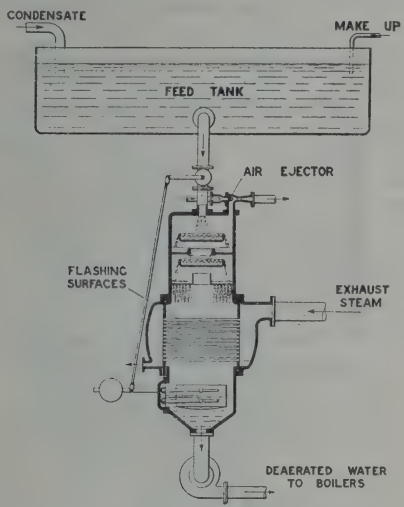

FIG. 59.

Fig. 59 shows one form of the 'Allen' de-aerator, in which the action of the vacuum in removing the dissolved gases is assisted by the spray falling upon steam-heated pipes placed across its path. The feed is thus heated as well as de-aerated in the same vessel.

A chemical method is exemplified by the Kestner De-gassing Plant.

THE KESTNER DE-GASSING PLANT.

(Kestner Evaporator and Engineering Co., Ltd.)

Fig. 60 shows diagrammatically one form of this plant.

The de-oxidising of the water is effected in the central portion of the vessel, which is filled with finely divided steel specially prepared both in respect to chemical composition and physical condition, so as to be readily oxidisable.

The apparatus is so proportioned that after passing through the de-gassing medium the water contains no oxygen capable of injuriously affecting the boiler, economiser, or pipe connections.

The water inlets (1) and outlets (2) are so arranged on the vessel that the flow of water may take place either upwards or downwards.

By arranging for a periodical reversal of the flow, portions of the material, which are most rapidly oxidised with the flow in one direction, are rested when the flow is reversed. During this period of rest a chemical change in the film of oxide takes place, the film being partially converted into a different form of oxide, which is easily detachable from the material.

A steam injector (6) is provided on the vessel through which steam is injected, causing sufficient turbulence to detach the oxide from the material. The flow of water carries the oxide through the filters (4), which retain the oxide, the cleansed water being returned to the feed reserve tanks. The operation of cleaning requires only a few minutes and involves no waste of water.

By changing the direction of flow every 24 hours, the de-gasser is kept in proper working condition, and will continue to function satisfactorily until the deoxidising material requires renewing.

For make-up water containing the usual proportion of dissolved oxygen, the makers state

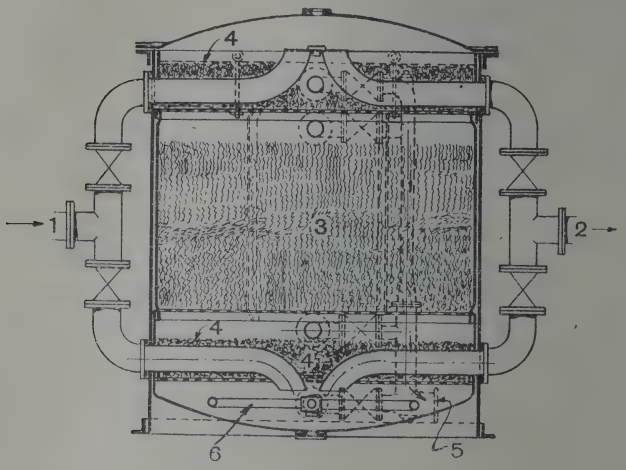

FIG. 60.

that the consumption of material amounts to about one ton for 100,000 tons of water. When the condensate is returned in a closed circuit, in which one of these de-gassers is included, a consumption as low as one ton of material for 1,000,000 tons of water may be obtained.

THE WEIR FEED-WATER DE-AERATOR.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

This de-aerator is designed on what is known as the 'flashing' principle—the water to be treated is heated and then passed into a vessel which is maintained at a vacuum higher than that corresponding to the temperature of the entering water. The energy liberated due to the fall in temperature causes the water to be disintegrated and the air liberated. The distinctive feature of the Weir de-aerator is that the flashing takes place in two stages, and is proportionally divided between each stage.

FEED-WATER HEATING

If heat which would otherwise be partially or wholly wasted be applied to heat the feed-water before it enters the boiler, an obvious saving is effected, since the amount of heat required to generate each pound of steam in the boiler is reduced. Even if the feed heating is carried out by means of steam withdrawn at low pressure from the engine or turbine, the gain by feed-heating may more than counterbalance the expenditure of steam.

The exhaust from auxiliaries is frequently used with advantage for feed heating.

Apart from questions of economy of fuel, feed heating is beneficial, as it reduces the temperature variations in the boiler, and thus also reduces the temperature strains. Also preheating the feed-water facilitates the removal of impurities and reduces the deposits in the boiler.

Assuming that heat which would otherwise be wasted, is used for feed heating, the saving may easily be calculated, as shown in the following example:—

Steam pressure 160 lbs. per sq. in.

Heat to generate 1 lb. steam from water at 60° F.
= 1203 — (60 – 32) B.Th.U. (see Steam Tables, p. 1593)
= 1175 B.Th.U.

If feed is heated to 200° F., the heat to convert 1 lb. of this hot feed into steam

$$= 1{,}203 - (200 - 32) \text{ B.Th.U.} = 1{,}035 \text{ B.Th.U.}$$

The saving is $\frac{1{,}175 - 1{,}035}{1{,}175} \times 100 = 11{\cdot}9$ per cent.

In general, if t_1, t_2 are the temperatures of the feed-water before and after heating, and H the total heat of the steam, whether saturated or superheated, the saving is

$$\frac{t_2 - t_1}{H - (t_1 - 32)} \times 100, \text{ per cent.}$$

The Row Feed-Water Heater

(Royles, Ltd., Irlam, near Manchester.)

In Row's Patent Feed-Water Heater, figs. 61 and 62, a peculiar form of indented tube is used, which it is claimed is *twice as efficient as an equal amount of plain tube surface*, giving great *compactness* and *efficiency*. The tube is also elastic in the direction of its length, thus avoiding liability of fracture or breakage when fixed between tube plates.

Fig. 61.

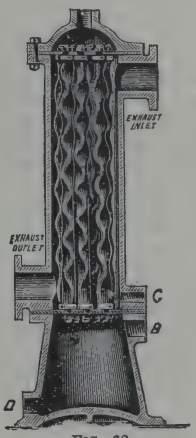

Fig. 62.

The Heater (fig. 61) shown is intended for good water—i.e. water not liable to scale—in which case the water is sent *through* the patent tubes. For bad water the order is reversed, i.e. the exhaust is sent through the tubes and the water circulates in the casing.

The Drayton Regulator and Instrument Co., Ltd., West Drayton, manufacture spirally corrugated tubes (fig. 63) fitted with plain copper ends for fastening to tube plates. These

Fig. 63.

tubes possess over 60 per cent. more surface than plain tubes of the same mean diameter, and are particularly useful where space for feed-water heaters is limited.

The 'Hudson' Economiser or Exhaust Steam Feed Heater.

This heater, which is also a steam condenser, is of simple construction, and, having no tubes, is claimed to cost nothing for renewal of parts.

The manufacturers state that the special features of this apparatus are :—

1. It extracts the grease from the exhaust steam *before* the latter comes in contact with the cold feed, and thus purified steam is obtained. This is important, as it is said to be impossible to perform the operation of separating the grease from the water afterwards without incurring considerable and constant expense.

2. The *purified steam* comes into direct contact with the *cold* feed (which enters the top chamber of the machine through a patent spray), the water being boiled, a large proportion of the carbonates and other impurities are thrown down, and these are easily removed through the manhole. Thus softened water may be obtained, *absolutely free from oil*, at a temperature of from 200° to 210° F. suitable for boiler feed, and, if required, a large surplus of hot softened water for washing and various other purposes may also be obtained by condensing the whole of the exhaust steam.

In many cases this softened water (free from oil) is being used for cask-washing in breweries, also in public baths, laundries, dye works, mineral-water factories, ice-making works, etc.

By use of this economiser, *incrustation* is entirely arrested before the feed-water enters the boiler, and generally the use of a metal brush may be substituted for the costly chipping of scale from the interior of the boiler shell. In this way a large saving is effected, and the apparatus by reason of this fact alone is of great value to steam users.

A report on *economy trials* by Professor T. H. Beare, M.I.C.E., showed an economy of fuel of 18·8 per cent. by the use of the economiser.

Automatic Temperature Regulation.

In heating feed-water it is essential to prevent the water being heated to boiling point, as at that point difficulties arise with feed pumps and injectors. By the use of automatic temperature regulators the predetermined feed-water temperature may be prevented from being exceeded. Automatic temperature regulators can be divided into two main groups: (1) Self-contained regulators producing their own operating energy for actuating valves, dampers, and such like; (2) indirect acting regulators in which the heat impulse merely brings into play an outside operating medium, which may be water under pressure, oil under pressure, compressed air, or electricity.

Self-contained regulators can work by vapour pressure obtained from a liquid with low boiling point, or by positive liquid pressure of an expanding liquid with a boiling point lying above the temperature for which the regulator is used. Vapour pressure regulators are limited to temperatures at which the vapour pressure is not too high, whilst liquid type regulators are limited to temperatures for which liquids with suitably high boiling point can be obtained. For temperatures above the limits of the vapour and liquid self-contained type, indirect regulation must be resorted to. In indirect regulators using air or liquid under pressure for the main regulation, a very small pilot valve only has to be actuated to control the main pressure, which can generally be effected with a very slight heat impulse, obtainable from a thermostat composed of two dissimilar metals. For temperatures which metals will not withstand without serious deterioration in a very short period the heat impulse must be obtained from electric pyrometers, which through at least two relays may operate either motors or powerful solenoids.

The 'Drayton' V.T. and M.S. Automatic Temperature Regulators.

(*The Drayton Regulator and Instrument Co., Ltd., West Drayton.*)

Fig. 64 shows the 'Drayton' V.T. Regulator, which is operated by the pressure of a volatile liquid in the bulb, acting through capillary tube on to a seamless metal bellows.

A spring opposing the action of the bellows determines the temperature at which the regulator will operate, and by varying the adjustment of the spring, a regulating range of 40° F. can be obtained.

Fig. 64A shows the 'Drayton' M.S. Air Operated Regulator, which is suitable where control within close limits is desired.

In this regulator the pressure of a volatile liquid or inert gas contained in the bulb acts on a diaphragm, which actuates a pilot valve controlling the supply of compressed air to the main diaphragm operated valve.

The principle of this regulator is shown by fig. 64B.

The Drayton Regulator and Instrument Co., Ltd., also manufacture regulators suitable for operation by water instead of compressed air, and time temperature regulators in which the temperature adjustment is operated by clockwork, so that any desired temperature curve may be reproduced.

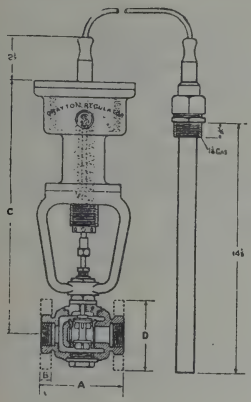

FIG. 64.—'Drayton' V.T. Automatic Temperature Regulator.

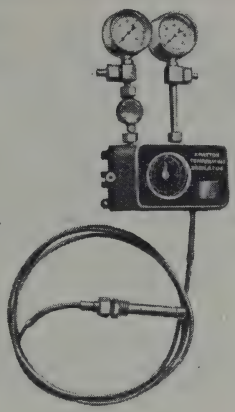

FIG. 64A. 'Drayton' M.S. Automatic Temperature Regulator.

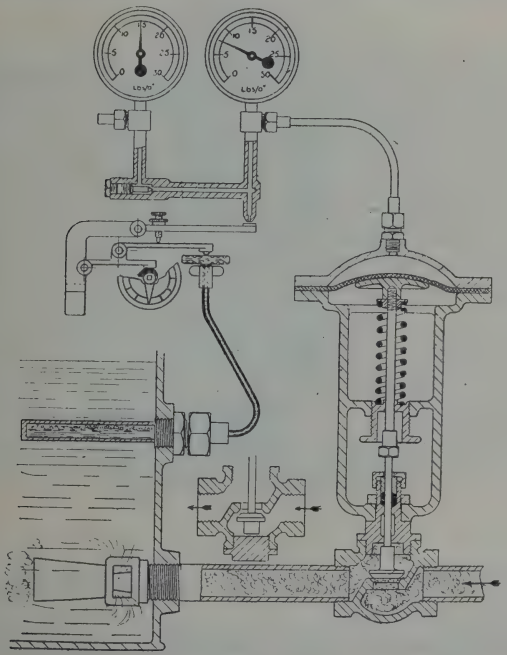

FIG. 64B.—'Drayton' operating principle of M.S. Regulator.

ECONOMISERS.

General Notes.

The term 'economiser' is usually applied only to those feed-water heaters in which the heat is obtained from the boiler flue gases before they pass to the chimney.

The standard pattern for pressures up to 250 pounds per square inch is represented by the Green and similar economisers.

For the latest turbine practice, with pressures of 350 to 450 pounds per square inch, steel pipes are used, and it is becoming usual to design the economiser as an integral portion of the boiler unit. In this sense there is no economiser, but only an equivalent addition to the boiler heating surface. An alternative method is to use cast-iron pipes of moderate surface, sufficient to heat the water to about 200° F. A rotary pump then delivers the water into the boiler proper. The aim of this arrangement is cheapness and the use of standard plant.

Economiser surface can decrease almost inversely as the gas and water velocities, and in fact follows very much the same laws as for boiler and superheater surface.

When using very cold feed, below 90° or 100° F., it should be preheated to 100° F. by live or other steam, before passing to the economiser, or the pipes will usually sweat, and serious external corrosion take place.

The 'Green' Economiser.

The 'Green' Fuel Economiser, fig. 65 (*E. Green & Son, Ltd.*), consists of a series of sections or rows of cast-iron tubes 4 ½ ins. in diameter and 9 ft long, placed in an enlarged part of the main flue, the tubes being fitted on their external surface with slow-moving scrapers. The sections are from 4 to 12 tubes in width, and the usual number of tubes is 96 per Lancashire

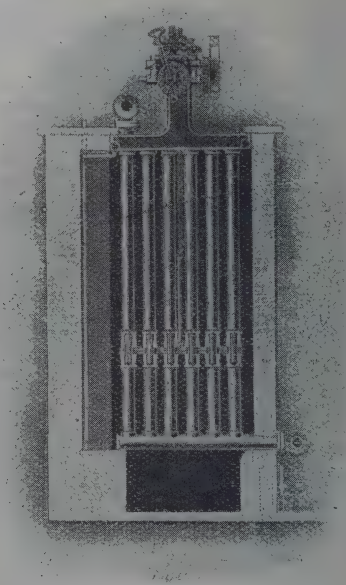

Fig. 65. The 'Green' Economiser.

boiler. When of large size the economisers are divided into a series of groups of 72 or 96 tubes each. The temperature of the waste gases may be reduced from 650° F. to 350° F., and the feed-water heated to a temperature of from 225° to 300° F. It is not advisable to feed an economiser with water at a lower temperature than 100° F. When the feed-water is colder than this, a small pipe should be led from the heated feed into the entering water, thus raising the temperature by mixture. This prevents external corrosion of the tubes, and improves the action of the scrapers.

for economiser tubes.

Booklets describing any or all of these may be had on application. Please mention this book.

E. GREEN & SON, LTD., WAKEFIELD
ENGLAND

F. 1705

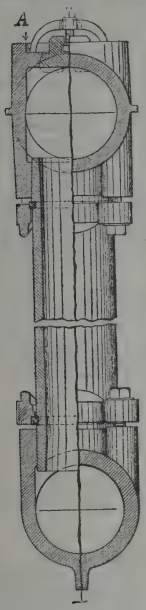
The weight of the economiser is about 1 ton for each eight tubes. Its water capacity is 6½ gallons per tube, and its heat-absorbing surface 10 sq. ft. per tube. The general rule is to provide 4 tubes per ton of coal per week (56 hours). Another rule is to provide 1 tube for each 3 indicated horse-power, but a more accurate standard by which to calculate the size of the economiser required for a given boiler plant is the evaporative capacity of the boilers.

This economiser is claimed to effect a saving in coal varying from 15 per cent. to 20 per cent. in ordinary practice.

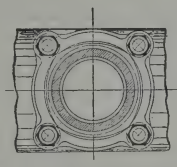
Green's Patent Ringstay Economiser

(for High Boiler Pressures).

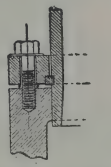
Extreme boiler pressures have made necessary certain alterations in the design of the standard economiser, which, although suitable in every way for normal pressures, does not provide for the higher pressures now met with. The chief alterations are: The staying of a certain number



Sectional View through Headers.



Plan of Ringstay Joint.



Details of Ringstay Joint showing Set-screw.

FIG. 66.

of socket joints in each section; a reduction in the diameter of the internal lid; a reversion to the circular type of top header, in place of the flat-topped rectangular design.

The Ringstay Joint, fig. 66, consists of an external ringplate and split ring threaded on to the end of the tube. The ring is held firmly to the shoulder of the tube by the ringplate, which is secured to the header by four set screws. Direct-pull tests have demonstrated that each of these joints is capable of sustaining a load of over twenty tons, irrespective of the friction of the tapered joint.

The lids are of the usual internal conical design, but of smaller diameter than the standard internal lid. The lid hole 'A' is stepped, so that if a tube requires replacing the metal can be more readily reamered out, the original lid being replaced by one of external type.

The lid holes are of sufficient diameter to enable the tubes to be cleaned, and as the headers are of the extended type, every tube can be inspected without breaking the top branch pipe joints.

One master lid is fitted into each top header.

The headers are of circular design, thereby ensuring a greater resistance to extreme internal pressures, and conforming in this respect to the best practice.

All the component parts are carefully examined, tested, and gauged before being used.

Green's Patent Tri-Tube Horizontal Economiser.

Green's Patent Tri-Tube Economiser was originally designed for erection in a horizontal position over modern types of water-tube boilers. In the space of a few years, however, it has become the standard type of economiser for modern high-duty, high-pressure boiler plants, and is installed either above or behind the boiler as necessary.

The economiser is constructed of cast iron of remarkably high tensile strength, while the patent Ringstay Joint increases by 100 per cent. the holding power between tubes and headers. The great resistance of cast iron to corrosive influences is well known and appreciated, and constitutes one of the chief reasons why Green's Tri-Tube Economisers are almost invariably specified for new installations. The success attained by this type of economiser is evident from the fact that it has been adopted at some of the largest electricity undertakings in the world. (List on application.)

Description.—The whole economiser, with standards and connecting bends, can be arranged to rest on the boiler supports, or, if desired, on independent joists, and can be fitted inside existing casing or provided with separate casing of Green's design. The sections are of such dimensions that they can be installed to suit almost any requirements and are interchangeable.

Sections.—Three tubes pressed into a front and back header constitute one section, and each is supported independently on vertical standards provided with projections on which the headers lie flat. There is ample room for expansion between adjacent headers and between the header ends and the standards.

Circulation of Water.—The number of sections in height or width of the economiser is decided by the dimensions of the boiler-casing. The water may pass through the bottom row of tubes, return along the next, and pass through each successive layer of tubes in series, or, on the other hand, it may enter the lowest two or three rows simultaneously, return along the next two or three in parallel, and so on throughout the remaining rows, thus putting the economiser partly in series and partly in parallel, as may be desired.

Each header is in itself horizontal and of small dimensions, consequently the temperature of the water from end to end is uniform and the expansion regular throughout the casting.

Baffling of Gases.—In modern high-efficiency boiler plants the economiser should be arranged to give as nearly perfect contra-flow conditions as possible, *e.g.* gases and water should flow in opposite directions. The special construction of Green's Tri-Tube Economiser readily permits of this.

Economiser Data.*

The present standard design of economiser has been practically the same since the first inception, and it would seem to be a very difficult matter to suggest any real improvement on the original design.

The economiser pipe is usually of a standard dimension of 9 ft. length and 4 $\frac{5}{16}$ ins. external diameter, being constructed to suit the boiler pressure and tested by hydraulic pressure to, say, 200 lbs. over working pressure. Each of these standard pipes has approximately 10 sq. ft. of heating surface, holds 6$\frac{1}{2}$ gallons of water and weighs $\frac{1}{3}$ ton. The power required to drive the scrapers is very small, being, for example, about $\frac{1}{2}$ h.p. for a set of 96 tubes. Cast iron is the most suitable material for the tubes, at any rate up to 300 lbs. steam pressure, as steel, wrought iron, copper, brass, etc., will not resist so well the corrosive action of the hot gases.

Makers recommend an installation large enough to hold one hour's supply of feed water in the pipes. Thus if a boiler is evaporating 650 gallons per hour, each tube holds 6$\frac{1}{2}$ gallons, and the number of economiser tubes would be then 104. When the evaporation is not known it is customary to allow 4 pipes for every ton of coal burnt per week of 54 hours, or one pipe for every 3 i.h.p. developed.

Out of 250 boiler plants (see page 1618) only 155 were fitted with economisers, the other 95 having no means of utilising the waste heat from the boiler flues. In these 155 plants, the exact average saving obtained was 11·4 per cent. of the coal bill. In actual practice, therefore, only about 17 per cent. of the plants fitted with economisers were saving 15 per cent. or over of the coal bill, whilst over 30 per cent. were saving less than 10 per cent., the true average for the whole 155 plants being 11·4 per cent. as stated.

---

* Abstract from 'Exact Data on the running of Steam Boiler Plants.' (D. Brownlie, B.Sc. Hons. (Lond.), F.O.S., J. Compston, and H. W. Royse; *Engineering*, November 1, 1918.)

The average figures from the 155 plants added together showed a beneficial rise in temperature the feed-water of from 115 deg. F. before the economisers and 241 deg. F. after, *i.e.*, an average e of 126 deg. F., equivalent to 11·4 per cent. saving. The corresponding fall in the flue gas nperatures from the 155 plants were 581° F. before the economisers and 389° F. after.

The reason the average figures for the actual saving are only 11·4 per cent. is not the fault the economiser as an appliance, but is due to the fact that the economical generation of steam scientific lines is not understood, and economisers generally are not installed on correct lines. e economiser is an absolutely essential part of any up-to-date boiler plant, and the saving tained should be 17½ per cent. to 20 per cent. under average conditions.

Other advantages of the economiser are the reduction of the strain on the boilers by the ovision of a high-temperature feed water preventing unequal expansion and contraction, and o that there is always a large reserve of hot water at hand for any sudden demand for steam. rther, the evaporative capacity of the boilers is greatly increased.

The chimney, as a draught producer, is an unscientific and wasteful method of creating a aught, depending for its efficiency on a great waste of heat. If this waste is utilised to the l by the economiser then the draught is curtailed and it is impossible to burn the necessary nount of coal to maintain the evaporation, in spite of the assistance of the economiser. There e many boiler plants that are forced, for this reason, to open slightly the by-pass dampers d allow a portion of the hot gases to go straight up the chimney to waste, so as to maintain raught to burn the amount of coal required to keep up steam. The mere installing of economisers rule-of-thumb lines may therefore in some cases be of little real advantage. This difficulty however, of little or no importance in the case of mechanical draught.

The water delivered into the economisers should not be over, say, 5 deg. to 6 deg. hardness, nen all encrustation troubles will be at an end.

Thousands of economiser pipes have been rendered useless in a few years because of corrosive tion. One remedy is to ensure that the feed water does not enter the economiser at a tempera- re of less than 100 deg. F., by providing an automatic circulating arrangement to take con- nuously a small portion of the water from the hot end and mix it with water from the cold d.

TABLE SHOWING RESULTS OF WORKING WITH ECONOMISERS.

Division according to Saving Obtained.	No. of Plants.	Average Temperature of Feed-water.		Average Temperature of Flue Gases.		Draught in Inches. W.G.		Steam Press Gauge.	Total Evaporation on Plant per Hour.	No. of Tubes on Plant.

Total plants .	250									

Some large economisers are now made with tubes 11 ft. long.

For high-pressure plants two feed pumps may be used, one being interposed between the economiser and the boilers. Thus the economiser does not have to stand the full boiler pressure. By this means also an economiser weakened by corrosion may be retained in service where otherwise it would have to be scrapped.

For the pump between economiser and boilers a turbine pump driven by a steam turbine is suitable.

AIR HEATERS FOR BOILERS.

The preheating of the air supply to boiler furnaces has recently attracted attention, and the system has been applied in several power stations.

The air is heated by flue gases, but the recovery of heat from these gases is not the only gain, for in addition the effect of preheating the air is to increase the furnace temperature, increase the completeness of combustion of the fuel, and increase the efficiency of the boiler.

It is claimed that each 20° to 30° F. of increase of air temperature will result in at least 1 per cent. saving of coal, and that an efficient air heater is superior to an economiser and less expensive. Having regard to the desirable temperatures of feed-water and of air supply, it is possible that the best plan may be to recover part of the heat of the flue gases in an air heater and part in an economiser.

LJUNGSTRÖM AIR PREHEATER.

(J. Howden & Co., Ltd., Glasgow.)

A recent development in the application of heated air to land boilers is the Ljungström Air Preheater. It is possible with this arrangement to extract from 70 per cent. to 75 per cent. of the heat contained in the flue gases and to return it to the boiler furnace, reducing the temperature of the exit gases to the neighbourhood of 200° F., giving boiler efficiencies up to 86 per cent., according to circumstances. Such a result could not possibly be obtained by a water economiser without very heavy capital cost for the economiser itself and the brickwork.

The space occupied by the Ljungström Preheater is comparatively small, and considerable reduction in the cost of buildings may be obtained by installing the Ljungström Preheater instead of economisers; the total reduction in capital cost may thus be very great.

A description of the Ljungström Preheater will be found on p. 2384.

THE 'GREEN' RECTANGULAR TUBE AIR HEATER.

This Air Heater has been designed to meet a demand for a heater of *light construction, economical proportions, maximum efficiency*, and *long life*. It consists of a number of elements grouped together *end to end, side by side*, and *one above the other*, in such a manner as to provide for a maximum amount of heat transmission with a minimum loss of pressure and draught.

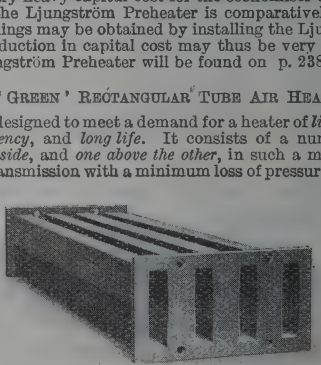

FIG. 67. One element: one-tenth full size.

Each element, fig. 67, comprises four rectangular tubes cast in one piece with a flange 10 in. × 5½ in. at each end. The tubes measure internally 2 ft. 6 ins. long, 4 ins. deep and 1 in. wide, and are 1½ in. apart, the complete element having 9·5 sq. ft. external and 8·33 sq. ft. internal heating surface. The flange faces of the elements are machined, and intermediate pairs of flanges are held together by bolts. The boundary flanges on the air inlet and outlet sides are bolted to suitable airtight sectional framework, with a converging mouthpiece opposite each tube in order to prevent undue eddying of the air (see fig. 68).

Each element weighs approximately 80 lbs; this is heavier than a heater of the same surface constructed of thin sheet-iron plates, but when it is remembered that the life of thin sheet-iron plates is only about one-tenth of the life of a cast-iron heater, a little extra weight is a decided advantage.

The space occupied by one element is slightly under 1 cu. ft.; consequently, a heater of sufficient capacity to supply the requisite quantity of air at a high temperature to the grate of a water tube boiler, need not take up more than 3 or 4 feet head-room, casing included, as the whole of the top of the boiler—being otherwise waste space—can be covered with these elements.

Accessible over the whole of the top surface of the boiler, a shallow heater can be inspected and cleaned with the greatest ease.

The elements are so arranged in the flue or uptake that the gases transversely sweep the flat surfaces of the tubes, which are arranged at 2½ ins. centres with, as already stated, 1½ in. spaces between adjacent tubes. The air, therefore, passes through the tubes in streams 4 ins. × 1 in. cross section, and the gases pass outside the tubes in streams 1½ in. in width.

The gases and the air to be heated can be made to pass either straight through the heater or through the several portions of it in series, according to the temperature and volume of air

required, and the weight of the gases at disposal. The design ensures, however, that both air and gases pass through the heater to the best advantage and with the least possible loss in pressure.

Fig. 68 shows a heater arranged immediately over a water tube boiler. Owing to the small amount of head-room taken up, it can be very easily cleaned, hand holes being arranged both in the top and sides of the casing.

The blowing off of the soot from a heater of this description is neither a lengthy nor a difficult process.

Cleaning doors in the side of the gas chamber admit hand lances for soot blowing by means of compressed air or steam.

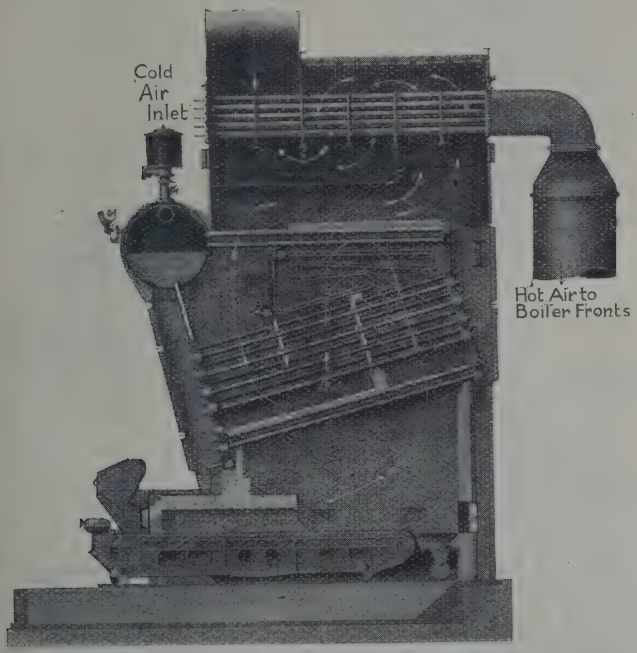

FIG. 68. 'Green' Rectangular Tube Air Heater over a Water Tube Boiler.

If desired, cleaning can be done from outside by means of fixed or revolving steam or compressed air pipes, so arranged that jets will play on or sweep practically the whole of the surface.

Hand cleaning holes can be provided in the top of the casing to give direct access to the upper part of the heater.

A large access door is recommended for entrance to the top of the heater should occasion necessitate.

The heater has no moving parts, and is therefore highly suitable for power stations where the number of necessary auxiliaries requiring close attention has become a serious problem.

THE GALLOWAY 'SUPERMISER.'

(Leek's Patents.) (*Galloways Ltd., Manchester.*)

The 'Supermiser' (figs. 69 and 70) is a combined air heater and economiser, that is, it serves to preheat the air for combustion and at the same time to heat the feed water, the heat for both these purposes being derived from the flue gases.

The apparatus contains a number of pairs of concentric tubes; the hot flue gases pass through

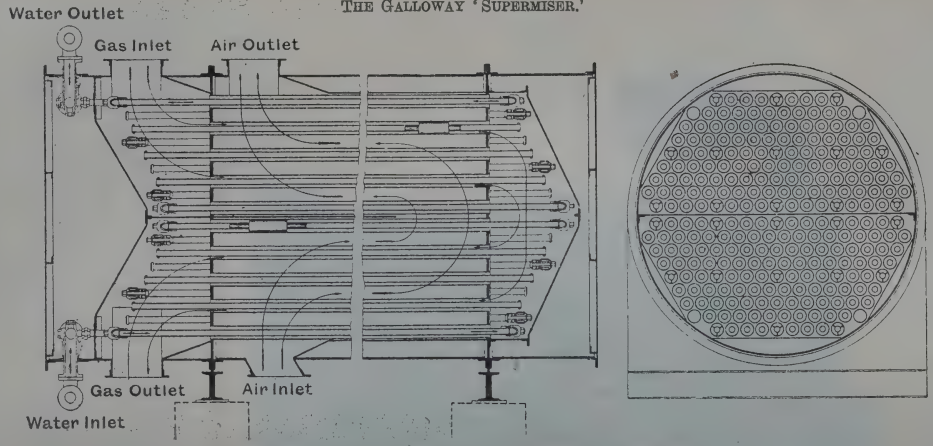

FIG. 69.—Section through 8 ft. 6 in. diameter 'Supermiser.'

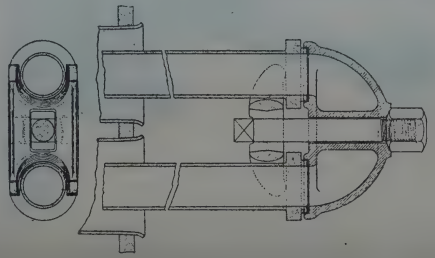

FIG. 70.—Section through header of 'Supermiser.'

the annular spaces between the inner and outer tubes, the air surrounds the outer tubes and the water flows through the inner tubes. The gas flows in the opposite direction to that of the air. The gases thus give up heat simultaneously to the water and to the air.

The rates of flow are intentionally high so that the rates of heat transmission are high, and thus the heating surfaces required are comparatively small, and the whole appliance is compact.

The tubes are carried between tube plates in a horizontal steel shell. The tubes are expanded into the tube plates at one end, but are merely a close fit at the other so that expansion and contraction due to temperature differences can take place freely.

The water tubes are supported inside the air tubes by thin radial fins parallel to the tubes, so designed as to offer minimum resistance to the gas stream, and are connected in series by headers of cast steel or of malleable cast iron.

The headers have removable caps and can themselves be quickly detached from the tubes. Ample opportunity for inspection and cleaning and, if required, removal of the tubes is thus provided.

There is a horizontal division plate about the centre of the Supermiser, which extends from the tube plate at the front end (the end at which are the gas and air branches), but which at the other end leaves sufficient passage-way for the air to pass from the lower to the upper half. The courses of the air, gas, and water are clearly indicated in the illustration.

The details of construction are carefully thought out, particular care being given to the avoidance of sudden changes of section of the gas path. This ensures that there shall be no ' dead pockets ' where dust and soot can be deposited. At the end inspection doors give ample access to the end boxes ; the headers and tubes can be fully exposed for inspection and cleaning.

The high speed of the gas through the tubes not only gives high rates of heat transmission, but prevents the deposition of the solid particles contained in the gas.

In large Supermisers the water divides into two or more circuits, in each of which the tubes are connected in series.

The high gas and air speeds involve considerable resistance in the gas and air passages and fans are provided to suit ; mechanical draught would in any case be necessary on account of the low temperature at the chimney. Results have proved, however, that the economies due to the Supermiser amply repay for the power and cost of the fans.

The gas fan is placed near the gas outlet, producing a suction and delivering the gas to the main flue through which it passes to the chimney.

The air fan takes air from the atmosphere, and delivers it under pressure to the Supermiser. The heated air, still at an inch or so of water gauge, is led through a sheet metal duct, properly heat insulated, to the front of the boilers, and enters the furnaces below the grates, still at slight pressure. The pressure is regulated by dampers at the boiler fronts, so that above the grates it is slightly below atmosphere, and thus the firedoors can be opened without risk for purposes of inspection or for hand firing.

No brickwork setting for the Supermiser is required. It may be placed over the flues or carried on a light steel staging.

The results obtained in practice have been very striking, the gas being cooled to a temperature below 250° and the overall efficiency of the boiler plant with an ordinary Lancashire boiler raised to over 80 per cent., which the makers are prepared to guarantee in all ordinary cases.

The possibility of corrosion of the tubes due to deposition of moisture has been considered. It must be borne in mind that owing to the uniform distribution of the gas streams, pockets of low velocity and low temperature are avoided, and hence the *average* temperature of the gas at exit, namely, say 250° F., is the lowest temperature of the gas at any part of the apparatus. Thus deposit of moisture is unlikely, and as a matter of fact has not been found in practice.

The high efficiency of the plant is accompanied by increased capacity. In cases where a boiler battery is overloaded, the installation of a Supermiser may relieve the situation and save the provision of an extra boiler.

Life of Boilers.

Lancashire and Cornish boilers last about 30 years, although there are cases in which Lancashire and Galloway boilers (with dirty, but not very scaly, water) have lasted for 50 years. Water-tube boilers (subject to a good deal of re-tubing) may be taken to last 20–25 years. Marine boilers, if properly treated and taken care of, should last at least 20 years under forced draught, and 25 years under natural draught.

The life of any boiler depends, naturally, upon the degree of care with which it is handled.

BOILER INSPECTION.

Boilers must be inspected once in every fourteen months. The owner or user may be made responsible for the effects of an explosion.

To prepare a boiler for inspection the manhole and mudhole doors should be removed, the blow-off cock closed, the steam valve locked to prevent tampering and danger to cleaners and inspectors, the hot feed valve locked, the bars and bridges removed from the furnace, and the flue doors removed and the hearth pit plates lifted away.

The flues and boiler plates in the flues should be swept clean of soot and dust.

The amount and nature of the internal scale should be observed, and the boiler thoroughly cleaned inside and scale removed.

The special points to be observed by the inspector are the condition of the plates along the seatings and all points of contact with bricks, the dryness of the flues, the absence of lime mortar nêar the plates, the dryness of the top covering, leakages at seams, circularity of furnaces, blisters, signs of overheating. Internally: grooving at plate junctions, around the angle irons of shell or furnace tube connection to end plates, at the root of angle irons or flanged seams or other points of stress or flexure, tautness of gusset stays, easy slackness of longitudinal stay bolts if present, condition of plates as to cleanliness, corrosion &c., condition of low-water appliances, scum troughs, feed pipes, gauge openings, and generally all points bearing on the safety of the boiler that may by some unlikely and hard to conceive contretemps lead to mishap of any sort.

In old boilers the openings in the shell should be looked to in order to ascertain the weakening due to removal of so much plate, and the degree of strength given back by added rings or other reinforcements. It is also desirable to note the quality of the attendance and workings of the boiler periodically, and to test the accuracy of the steam gauge and working of the safety valves.

The foregoing remarks apply more particularly to shell boilers. For water-tube boilers, the caps of the water tubes must all be removed, and each tube examined and seen through for scale deposit, and as far as possible externally for blisters. Locomotive-type boilers are not easy to inspect, should never have riveted shell seams below water line, and must be largely judged by the appearance of such parts as are visible. Every few years the shell should be examined internally, the fire tubes being removed for the purpose. The accessibility of a boiler for complete inspection ought to be a considerable factor in determining the choice of a boiler, and more particularly so when the water is dirty or corrosive in quality.

Experience is necessary to make a good inspector. He must possess judgment and sense of proportion, and be able to order a boiler not to be worked until further notice, without it being possible for further enquiry to show that there were not good grounds for his fears.

BOILER EXPLOSIONS.

The following table gives the description of the boilers which have exploded or collapsed during the thirty-nine and a half years from June 1882, when the first Boiler Explosion Act came into operation, to December 1921, and the causes of the explosions and collapses.

Type of Boiler.	Land Boilers.		Boilers Afloat.		Cause of Explosion or Collapse.	Land Boilers.		Boilers Afloat.

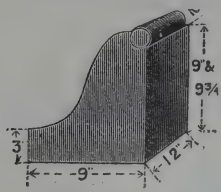
Firebrick Makers,
STOURBRIDGE.

F. 1712

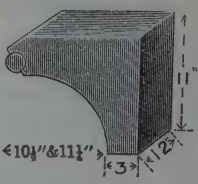
MODERN METHODS OF SETTING STEAM BOILERS BASED ON EFFICIENCY.

PATENT ASBESTOS CUSHIONED SEATING BLOCKS.



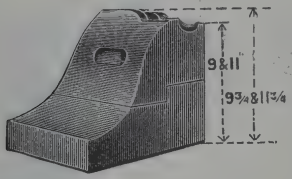
No. 1. Short 9"; Long 9¾"

PATENT ASBESTOS CUSHIONED FLUE COVERS.



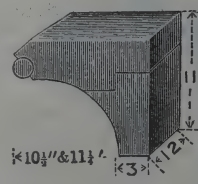
No. 11. Short 10½"; Long 11¼"
With or without Pyrometer hole.

PATENT ASBESTOS CUSHIONED SEAM INSPECTION SEATING BLOCKS



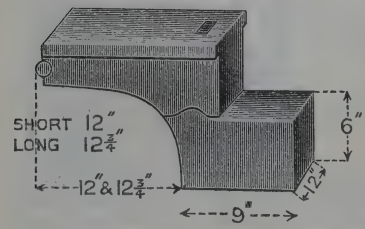
No. 3. For 9" & 9¾" Seating Block, Right hand. Made also Left hand to match.

PATENT ASBESTOS CUSHIONED SEAM INSPECTION FLUE COVERS



No 11. Short 10½"; Long 11¼"

PATENT ASBESTOS CUSHIONED REMOVABLE FLUE COVER



Alternative top portions of cover are spigoted and rebated.

Also made for Side Flues 9" wide
Short 9" Long 9¾"

PATENT INTERLOCKING ARCH BRICKS AND MANHOLE BLOCKS FOR DOWNTAKES.

N.B.—All the above can be obtained from stock. We also supply all types and patterns.

E. J. & J. PEARSON, Ltd., STOURBRIDGE.

F. 1713

BOILER LEGISLATION.

The Boiler Explosions Acts, 1882 (45 & 46 Vic. ch. 22) and 1890 (53 & 54 Vic. ch. 35) provide for inquiry into boiler explosions. The Acts extend to the whole of the United Kingdom. The term 'boiler' means any closed vessel used for generating steam, heating any liquid, or receiving steam for heating, steaming or boiling, excepting boilers used exclusively for domestic purposes or in the service of his Majesty. On the occurrence of a boiler explosion, notice must be sent within 24 hours to the Board of Trade by the owner, user, or person acting for him. This notice to state the name of premises or works, postal address, day and hour of explosion, number of persons killed and injured, description of boiler, purpose used for, particulars of failure, working pressure, by whom last inspected, and by whom insured.

The Act of 1890 makes the Act of 1882 applicable to sea and mine boilers.

The judgment of the court of enquiry into the Greenwich explosion of Christmas 1906 has made it a serious matter for engineers who have not acquired the necessary experience by training to assume responsibility for steam boilers. Steam engineers should be in charge of steam plant and machinery, is the lesson of the verdict in that case.

BOILER FITTINGS.

Injectors.

To Compute the Diameter of Throat and Volume of Discharge.

d=diameter of throat in millimetres; V=volume of water required per hour in gallons
P=pressure of steam in pounds per sq. in.

$$d = \cdot 709 \sqrt{\frac{V}{\sqrt{P}}} \qquad V = 1 \cdot 985\ d^2 \sqrt{P}.$$

Example.—The pressure of steam is 200 lbs., and the volume of water required to be delivered per hour is 1,010 gallons.

Then $\cdot 709 \sqrt{\frac{V}{\sqrt{P}}} = \cdot 709 \times 8 \cdot 45 = 6$ mms.; and $1 \cdot 985\ d^2 \sqrt{P} = 1 \cdot 985 \times 36 \times 14 \cdot 142 = 1{,}010$ gals.

The above particulars apply to all properly proportioned live steam injectors.

The Penberthy Patent Injector.

The 'Penberthy' Injector (fig. 71) is a perfectly automatic arrangement; by this is meant that when the injector is working and forcing water to the boiler, if the current of water be suddenly broken by any cause, such as a sudden jar or jolt in the case of a traction engine or road roller,

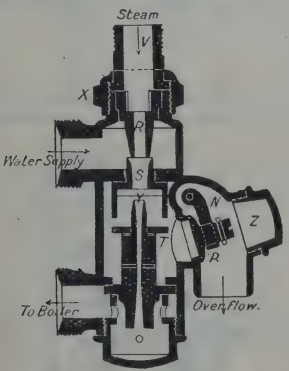


Fig. 71.

R, steam jet; O, plug; N, overflow hinge; S, suction jet; V, tail pipe; P, overflow valve; Y, delivery jet; X, coupling nut; Z, overflow cap.

or in the case of a marine boiler by the rolling of the vessel throwing the sea-cock out of the water for a moment, the injector will pick up the water and again establish the current to the boiler automatically, *i.e.* without the manipulation of a single valve or the least attention from an attendant. It is this quality which has made the 'Penberthy' so popular among marine

engineers and which has led to its adoption by the great majority of the traction and threshing engine manufacturers.

The Penberthy delivers water to boiler at 160° to 212° Fahr., according to temperature and steam pressure; but 200° to 211° can always be delivered at nearly all pressures over 50 lbs. by throttling the suction valve and delivering the minimum capacity.

The injector is made in fifteen sizes, from ⅜ in. to 2½ ins., and it is also supplied in three distinct styles to suit various positions. The maximum quantity delivered is from 80 to 4,200 gallons per hour according to size, and it is applicable to boilers up to 600 h.p. Sizes AA to CC are especially supplied for traction, portable, and ploughing engines. It is most efficient at the pressures of 50 to 80 lbs. (when with the valve wide open it will lift 20 ft.), although it will work at a lower pressure and also up to as high as 180 lbs. under favourable conditions. It is suitable for all classes of boilers. A *low-pressure* non-lifting pattern is supplied for steam pressures below about 20 lbs.; these injectors will start at from 1 to 3 lbs. steam pressure where water is taken from a barrel or tank at, or just above, the level of the injector. With water pressure of 20 lbs. they will start at from 10 to 12 lbs. low steam, but with two globe valves in water-supply pipe the pressure can be reduced and injectors started at correspondingly lower pressures.

A special pattern (Nos. 328, 332) also is being made in ½ in., ¾ in., and 1 in. sizes, for very high pressures—namely, up to 200 lbs. No. 328 AA. is used extensively for steam wagons and tractors.

For pressures to 240 lbs., and for hot-feeds, the Auto-positive type is supplied. This type has fine working parts, and combines the features of both the positive and the automatic injector.

Over one million of the Penberthy Injectors are in use.

POWER AND CAPACITY OF PENBERTHY INJECTORS.

Size.	Horse-power.	Pipe Connections.	Capacity per Hour. 1 to 3 ft. lift, 60 to 110 lbs. Steam Pressure.

(W. H. Willcox & Co. Ltd.)

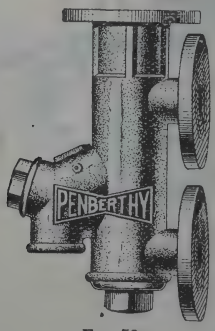

FIG. 72.

Owing to the increasing use of flange connections in this country, especially on fine works, the Penberthy Injector is now made up with flanges as shown in fig. 72. The working qualities

of the flanged injector are only slightly different from those of the screw-nipple machine, except that by the different construction of the body the high working pressure is brought up to 180 to 185 lbs. The injector with flanges is connected and operated in precisely the same manner as the injector with screw nipples. It is made in all sizes except ¼ and ⅜ in.

(*W. H. Willcox & Co. Ltd.*)

* These capacities can be reduced 40 per cent. by regulating water supply valve.

WILLCOX'S EJECTOR STEAM-JET PUMP OR WATER RAISER.

This ejector, fig. 73 (*W. H. Willcox & Co. Ltd.*), will lift water 20 ft. with any steam pressure above 25 lbs., and 25 ft. with pressure at 40 lbs. or over. On pressures above 80 lbs.

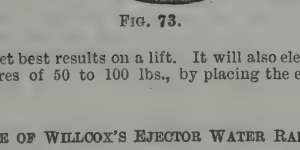

FIG. 73.

steam must be throttled to get best results on a lift. It will also elevate 50 ft. at 60 lbs. pressure, and 65 to 100 ft. on pressures of 50 to 100 lbs., by placing the ejector within 12 to 18 ins. of water supply.

The ejectors are also suitable for exhausting air from pumps to create vacuum, and are largely used for this purpose.

Notes on Injectors.

A very frequent cause of trouble is that by one means or another the injector becomes overheated and refuses to lift its water. This may be due to steam leaking past the check valve into the body of the injector, and then passing to the suction pipe, so that the latter becomes too hot. Under these conditions it is impossible to make the injector work. Another cause of overheating is sometimes to be traced to the proximity of the fitting to the hot boiler shell, which allows heat from the latter to pass to it by conduction and radiation. In the first case the remedy is to fit a well-made check valve, combined with a plug cock, between the injector and the boiler. This should be done, even if the former is designed with a self-contained back-pressure valve. Further, the plug cock should be shut off when the injector is not in use. In the second instance, it sometimes happens that an injector is employed which is fitted with its own back-pressure valve, and it is then bolted directly to the boiler. This is very bad practice, as a single valve is not dependable in the first place, and a further point is, that the injector is much too close to the hot boiler. This is a fruitful cause of trouble. Also, should anything go wrong with the injector, it is necessary to blow down the boiler before it can be put in order; whereas, with a combined check valve and plug cock, the latter can be closed, and the injector removed under steam.

An injector will not work satisfactorily if supplied with wet steam; therefore, in order to ensure that this is as dry as possible, it should be taken from the highest available point in the boiler.

Another defect sometimes arises through the check valve not having sufficient lift, or on account of some sort of obstruction in the delivery pipe. The effect of this is that the injector will lift the water, but on account of the greater pressure due to the obstruction against which it has to work, it will be unable to force the water into the boiler, which will consequently find an escape through the overflow instead.

In some cases the water supply to the injector is taken from a tank placed beside the boiler, on the boiler-house floor, the supply to the tank being from an external source, and controlled by a ball cock with a float attached, so that the level of the water in the supply tank is constant. This is a very satisfactory arrangement. In other instances the source of supply may be some little distance away, and connected to the injector by means of pipes. Further, if the water is taken from a well the level may vary between considerable limits. Hence, when purchasing an injector, it is of the utmost importance that the manufacturer should be given all possible data, such as the greatest static head and the length of pipe with the number of bends, so that he can obtain the total suction lift and supply an injector to suit the conditions.

Much trouble will be experienced if the feed-water is allowed to become hot. The lower the temperature the better. There are many so-called hot-water injectors, but even these will not prove very satisfactory if the temperature of the feed-water is allowed to rise too near to the maximum temperature specified by the makers. In order to prevent as much as possible any rise in temperature, it is of the greatest importance that the overflow from the injector should not be allowed to drain back into the feed-tank. An overflow pipe should be fitted that will lead this hot water clear of the feed supply. Such a pipe should not be closed, but should enter an open cup, similar to the overflow of the circulating water in a gas-engine jacket. It is then under constant observation of the man in charge, and if any irregularity occurs it is quickly detected.

Occasionally an injector will refuse to work, due to a leak in the suction pipe. If this defect is present it may be located by fixing a plug in the suction pipe and opening the steam supply to the injector, when the position of the leak will be easily detected.

Lastly, dirt and grit are a source of trouble at times. To prevent this as far as possible, a straining rose should be fitted to the suction pipe. This will not exclude all grit, and occasionally small grains of solid matter suspended in the feed-water will find their way through and lodge on the internal surface of the injector. Also if the water contains soluble salts of magnesium and calcium, it becomes heated on passing through the injector, and some of these salts are deposited, forming incrustations which may cause the injector to refuse to work, either because it has become totally choked up, or else small particles of the incrustations may break away and become lodged under the back-pressure valve or check valve and prevent its closing, when the injector will refuse through overheating.

It is always advisable to keep a spare injector in stock, and if the water contains a considerable amount of impurity, instructions should be given to change the injector at regular periods. The length of time that one should be allowed in continual service must be governed by experience with the particular conditions under consideration. In order to loosen the deposit the injector may be left to soak in diluted hydrochloric acid.

If the above very easily followed points are given attention, injectors will be found most reliable, and few complaints will be heard.

(*'Mechanical World.'*)

SAFETY VALVES.

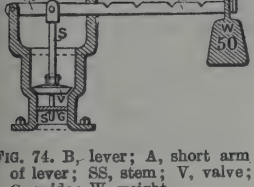

FIG. 74. B, lever; A, short arm of lever; SS, stem; V, valve; G, guide; W, weight.

WEIGHT ON SAFETY VALVES.

If A = area of valve in sq. ins., P = pressure in lbs. per sq. in., l_1 = distance of valve from fulcrum, l_2 = length of lever, w_1 = weight of lever in lbs., l_3 = distance of centre of gravity of lever from fulcrum, w_2 = weight of valve and stem in lbs.

Then W, the weight required at the end of the lever,

$$= \frac{P \times A \times l_1 - w_1 \times l_3 - w_2 \times l_1}{l_2}.$$

SAFETY VALVE AREAS.

Since the steam production of a boiler is sensibly the same at all pressures, and since the density of steam increases very nearly as the pressure, and since steam escapes at an outlet at practically constant volume, it appears that safety valves, like boiler stop valves, may be reduced in size as pressure increases. Ordinary valves have a very small lift. Special valves in which the steam reaction is utilised to increase the lift will give a much greater opening. If a valve lift a height equal to a fourth of its diameter the area of opening is equal to the valve area, and no greater lift would give greater output.

It is not sufficiently well known that boilers working at a low pressure require larger safety-valves than boilers at a high pressure. Thus, for example, a boiler working at 15 lbs. by the steam gauge requires three times the area of safety valve opening that is required by a boiler at 75 lbs. This is the more important when it is remembered that in a boiler which is safe only at low pressure, an additional 15 lbs. pressure doubles the strain, whilst in the boiler at 75 lbs. a rise of 15 lbs. adds but a fifth to the stress on the plates. This point as to the safety-valves on old low-pressure boilers is too little known or recognised.

Safety-valve areas should be inversely as the absolute pressure.

In well-proportioned dead-weight safety valves it is usually expected that if a pressure of 60 lbs. per sq. in. opens the valve, a pressure of 70 lbs. will keep it sufficiently open for the escape of all the steam produced.

The former Board of Trade rules are largely followed, and as they are more detailed, bringing out many points of importance, extracts are given below, also extracts from the rules of Lloyd's and Bureau Veritas.

BOARD OF TRADE RULES FOR SAFETY VALVES.

The area per square foot of fire-grate surface of the locked-up safety valves for boilers with natural draught should not be less than that given in the table (page 1719) opposite the boiler pressure intended, but in no case should the valves be less than 2 ins. in diameter.

When ascertaining the fire-grate area, the length of the grate should be measured from the inner edge of the dead plate to the front of the bridge, and the width from side to side of the furnace on the top of the bars at the middle of their length.

[*Note.*—The table corresponds to the formula $A = \frac{37 \cdot 5}{P + 15}$, where A = safety-valve area in sq. ins. per sq. ft. of grate, and P = pressure in lbs. per sq. in.]

Where forced draught is used, the area should not be less than $\frac{A}{20} \times$ estimated coal consumption in lbs. per hour per sq. ft. of grate.

The safety valves should be fitted with lifting gear, so arranged that the two or more valves on any one boiler can at all times be eased together, without interfering with the valves on any other boiler. The lifting gear should in all cases be arranged so that it can be worked by hand either from the engine-room or stoke-hole.

Care should be taken that the safety valves have a lift equal to one-fourth their diameter; that the openings for the passage of steam to and from the valves, including the waste-steam pipe, have each an area not less than the area according to the table; and that each valve box has a drain pipe fitted at its lowest part.

In the case of lever valves, if the holes in the lever are not bushed with brass, the pins must be of brass; iron and iron working together must not be used.

Too much care cannot be devoted to seeing that there is proper lift, also that free means of escape for the waste steam are provided, as it is obvious that unless the means for escape of the waste steam are ample, the effect is the same as reducing the area of the valves or putting an extra load upon them. The valve seats should be secured by studs and nuts.

At least two valves should be fitted to each boiler.

The springs and valves must be so cased in that they cannot be tampered with.

Provision must be made to prevent the valves flying off in case of the springs breaking.

The requisite safety-valve area must be cased in and locked up in the usual manner of the Government valves.

The size of the steel of which the springs are made must be in accordance with that found by the following formula.

$$d = \sqrt[3]{\frac{L \times D}{C}};$$

where,

L = load on the spring, in pounds;
D = diameter of the spring—from centre to centre of wire—in inches;
d = diameter, or side of square, of the wire in inches:
C = a constant, being 8,000 for round and 11,000 for square steel.

The springs must be protected from the steam and impurities issuing from the valves.

When valves are loaded by direct springs, the compressing screws must abut against metal stops or washers, when the loads sanctioned by the surveyor are on the valves.

The springs must have a sufficient number of coils to allow a compression under the working load of at least one quarter the diameter of the valve.

Spring-loaded valves are tested under full steam and full firing for at least twenty minutes with the feed-water shut off and stop-valve closed.

When the valves are of novel design, and the accumulation of pressure exceeds 10 per cent. of the loaded pressure, the case has to be specially reported upon by the surveyor.

Lloyd's Rules for Safety Valves.

(Abridged.)

At least two safety valves are to be fitted to each boiler, arranged so that springs and valves are cased in, that valves cannot be overloaded while steam is up, that the valves can be lifted by easing gear and turned round on their seats, and that valves cannot lift out of their seats if the springs break.

Vertical boilers with 100 square feet or more of heating surface to have two safety valves each not less than 1·5 in. diameter; those with less than 100 square feet heating surface one valve not less than 2 ins. diameter.

All safety valves of one boiler may be fitted in one chest connected direct to boiler by passage having cross-sectional area not less than half the aggregate area of the valves. Valve chest to be drained. The minimum aggregate area of safety valves of a boiler, coal- or oil-fired, in square inches

$$= \text{total heating surface of boiler in square feet} \times \frac{C}{p + 15},$$

where

p = pressure in lbs. per square inch;
C = 1·25 for boilers using coal;
C = 1·5 for boilers using oil and for those with closed stokehold forced draught.

Waste-steam pipe to have area not less than 1·1 times area given by above formula.

Safety valves to be set under steam. During test of fifteen minutes with stop valve closed and full firing conditions accumulation of pressure is not to exceed 10 lbs. per square inch.

Bureau Veritas Rules and Regulations for Safety Valves.

At least two spring safety valves of an approved design must be fitted to each main boiler.

The total area of the safety valves is given by the formula

$$A = \frac{8{\cdot}7}{\sqrt[4]{(P - 18)^3}},$$

where

A = sectional area of safety valve in sq. ins. per sq. ft. of grate surface; P = working pressure in lbs. per sq. in. No safety valve to be less in diameter than 1¼ in.

When forced draught or oil fuel is provided for, the area is to be increased in proportion to the increased evaporative power of the boilers.

Suitable arrangements and gear to be fitted in connection with the safety valves, whereby they may be lifted from the deck as well as from the stoke-hole floor.

BOARD OF TRADE RULES AND REGULATIONS FOR STEAMSHIPS.

SAFETY-VALVE AREAS. (*Abridged Table.*)

WATER GAUGES.

The breakage of a water-gauge glass in high-pressure steam boilers is fraught with danger, especially in places where the attendants are working in confined places from which it is difficult for them to escape, and any appliance which prevents the serious consequences arising from this cause is one of the most important and desirable safety fittings that can be attached to a steam boiler.

The Klinger High Pressure Water Gauge

(Richard Klinger, Ltd., 120 Southwark Street, London, S.E. 1.)

The latest type of this well-known gauge (fig. 75) is suitable for working pressures up to 1,000 lbs. per square inch, the great advantage of which is that it can be entirely dismantled whilst the boiler is under steam. This is made possible by the inclusion of an auxiliary plug, which can be screwed right home, thus shutting off the water and steam.

It is impossible to make a mistake in reading the gauge, as the water shows black and the steam silver.

These gauges can be supplied tipped forward at an angle of 30° for Babcock & Wilcox, Stirling, Vickers, and Thompson water-tube boilers.

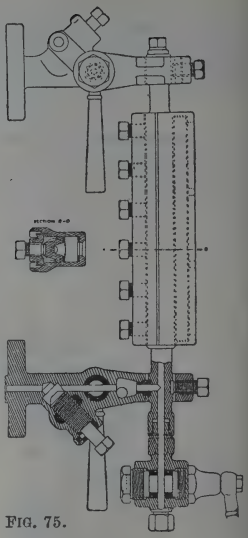

Fig. 75.

Fig. 76.

Hulburd's Cartridge Sight Glasses.

(Patent.)

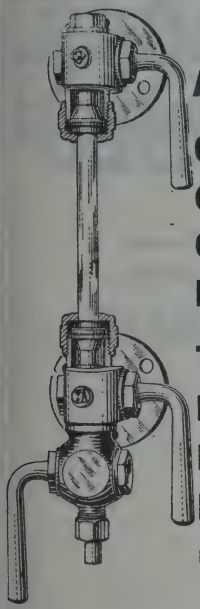
This (fig. 76) is a neat and efficient device for protecting and rapidly removing and replacing sight glasses in water gauges and sight-feed lubricators. In Hulburd's make of gauge frames and lubricators the glasses are packed at leisure in metallic guards or sheaths, each thus forming a self-contained 'cartridge' from which the system derives its name. In the event of breakage of a glass the complete cartridge, containing the broken fragments, is easily withdrawn while under steam, and a new one readily inserted in its place. The metallic guard or cartridge case enables all splinters of glass to be removed without danger to attendants, and permits the immediate screwing up of the gland nuts without the possibility of fracture, the metallic cartridge case receiving the gland pressure and completely protecting the glass tube within it. Suitable windows are provided in the cartridge case of ample size to afford an unobstructed view of the glass tube and contents, and in the case of gauges the back is arranged as a water level indicator of special design, which shows with peculiar distinctness the height of the water column and makes it impossible to mistake an empty glass for a full one.

'Woodite' Packing.

The material known as 'Woodite' (*The Woodite Co.*) is of a special secret composition to resist the action of high or low pressures, whether of steam or water, and is impervious to acidulated or other chemically impure fluids. 'Woodite' is made to any shape or size and of a quality or flexibility to suit the service to which it is to be applied. It has been extensively employed for conical gauge-glass rings, packing rings, pump valves, hydraulic packings, gaskets, etc., with most satisfactory results. The chief advantages of the Woodite conical gauge-glass and packing rings for steam users are their ease of application or renewal, the maintenance of a perfectly tight joint, the entire avoidance of unnecessary pressures on the glasses or rods, which causes breakages in the former and excessive friction in the latter, and the elimination of the dangers incident to steam or water passages becoming choked in the case of gauge glasses. On large slow-moving boiler feed-pumps these conical packing rings have shown excellent results and economy, working at 185 lbs. steam pressure with superheat, the piston rods being $3\frac{3}{8}$ ins. diameter.

Ordinary valve spindles packed with these packings will always be found free to move, no matter how long the valve has been idle.

WOODITE GAUGE GLASS RINGS.



Absolutely reliable for water and steam pressures.

Greatly prolong life of Gauge Glasses.

Overcome breakages due to excessive pressure.

Only require a few moments to install or renew.

Do away with all digging out of old packings.

The glass is only subjected to boiler pressures.

Hindrances to free passage of water or steam avoided

Impossible to overpack as with other packings.

Never adhere to nor corrode the glass.

Give ideal results under all conditions.

Data required—Internal and external (bottom of thread) diameter and depth of stuffing boxes, also outside diameter of gauge glass.

Adopted by H.M. Navy, War Dept., Foreign Navies, and most of the leading Steamships and Railway Companies in all countries as well as by Manufacturers and Steam Users generally.

THE WOODITE COMPANY, LTD.,

MITCHAM COMMON,

SURREY, ENGLAND.

Also Woodite for Pump Cups, Hydraulic 'U' Rings, Pump Valves Gaskets and Joints of all kinds, Sheeting, Hose, Belting, etc.

Defects in Water Gauges.

As ordinarily fitted, the gauge is usually attached directly to the boiler and provided with three taps, one connecting to the steam space, the second to the water space, and the third controlling the discharge to atmosphere. The latter should always discharge inside the boiler-house, where the effluent can be seen, and not be as it sometimes is, with a mistaken idea of cleanliness, coupled to a waste pipe, led outside, where the evidence of its action is not visible when the attendant opens the tap. It is of value to have duplicate gauges, as the cost is comparatively trifling, and one gauge serves as a check on the other. All three taps should be tested independently, that is to say, the bottom tap should be shut while the top one is opened and *vice versâ*, the top one shut while the bottom is opened, so as to give a thorough 'blow through' of the steam and water connections to the boiler. Unless this is done there is no certainty of the gauge being in working order, while there is risk of the top and bottom connections becoming choked and causing a false reading. More than one serious accident has been traced to defects in the taps themselves, owing to the holes in the plugs of the taps not coinciding with the thoroughfare of the fitting, so that when the position of the handle suggests the tap is open it is in reality nearly closed. Another cause of false readings is the blocking of the passage in the glass tube through the indiarubber packing ring working over the ends of the glass, owing to the glass being cut too short and the gauge not being provided with a nipple in the bottom of the gland to protect the glass against this risk. Having regard to the serious results which may attend overheating from shortness of water, it is advisable whenever possible to supplement the water gauge with a fusible plug, and if the boiler is a large one, with a low-water safety-valve as well. (*Mechanical World.*)

Gauge Glasses.

It is important to have the fittings exactly in line with each other, and to have them large enough so as not to cause the glass to bind or to be cramped in the least. When the fittings are not in line the glass is apt to be cramped either when putting it into the sockets in the fittings or when tightening the packing nuts. Wrenches should not be used for tightening the packing nuts around the gauge glass. When a glass is packed with the proper kind of packing and the nuts have been screwed up just tight enough to prevent leakage when both the glass and the packing have been warmed, the glass may readily be turned around in the fittings with merely the thumb and forefinger.

After putting in a new glass turn on a very little steam, leaving the drip at the bottom of the glass open so that the steam will gradually fill the glass and escape through the drip-cock. The glass is thus warmed thoroughly before the water is let into it and before it is subjected to pressure. When the glass has become thoroughly hot, open the steam valve wider, then open the water valve a like amount, and continuing to open both valves alike until fully open, then slowly close the drip at the bottom. This method not only allows the fittings to be thoroughly blown out, but enables the operator to increase the pressure on a new glass and new packing more gradually. It is best to anneal all the glasses before using them. This is generally accomplished by means of a water and steam bath, the water and the glasses being heated by steam. It is cheaper in the long run to cut glasses with a gauge-glass cutter than to attempt to cut or break them off with a broken file, or by similar means, because a slight nick in the glass at the wrong place may mean the early destruction of the glass when subjected to pressure and varying temperature. Some engineers fit a thin brass or copper thimble into the upper end of the tube, as shown in fig. 77, which prevents scale and water

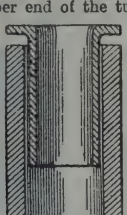

Fig 77.

Fig. 78.

from coming in contact with the glass when blowing out the latter, and hence it reduces the eroded and pitted appearance commonly seen at the upper end of unprotected glasses. Tubes made of aluminium may be obtained of dealers in engineers' supplies which accomplish the same result.

These tubes and thimbles, it will be seen, protect the inner surfaces of the glass only, and as the glass is liable to be crowded to one side or the other in the packing nut as well as in the fitting itself, it is a good plan to also protect the glass on the outside.

A simple means of protecting the glass on the outside is also obtained from dealers in gauge glasses. The arrangement consists of a rubber sleeve adapted to slide over the end of the glass, as shown in fig. 78. The glass cannot come in contact with the socket in the fitting, neither can the packing nut touch the glass when the packing is screwed up. The combination

the thimble and the latter device prevents the rapid wear of the glass at the top, and also retains the glass clear of all metallic contacts, which has been found to be very desirable where glasses are subjected to high pressure and temperature and sudden changes in the latter.

When the rubber protector is employed, separate packing rings are not needed, because the packing forms a part of the sleeve, as shown. Annealed gauge glasses protected inside and out by this or similar means will last as long under any circumstances as it is possible to make them by any means thus far made known.

If packing 'rings' are used, then in order to secure a tight joint with the least possible pressure, thus avoiding any tendency to break or to cramp the glass due to the packing, it is necessary to obtain a form of packing that will fit snugly in the space in the nut.

(*H. E. Waverly, 'Mechanical World.'*)

Superheated water acts on most varieties of glass as a violently corrosive agent, and for gauge glasses ordinary glass cannot be used. A special glass, under the brand 'Hercules,' to resist high pressure steam, is made by Joseph Tomey & Sons, Ltd., Birmingham. It is specially constructed of boro-silicate, and is made after the 'Jena' formula. The glass is practically white in colour and has withstood the following remarkable tests:—

After the glass had been submerged in iced water for five minutes it was plunged into molten lead, and showed no signs of fracture. It has withstood 4000 lbs. hydraulic pressure, and 750 lbs. steam pressure.

Although the glass was specially manufactured to meet the requirements of high-pressure and superheated boilers, it has been used for a great number of low-pressure boilers, because at low pressure the material is practically unbreakable and is considerably cheaper in the long run than the ordinary quality gauge glass.

Unbreakable Water Gauge.

A simple and effective form of water-level indicator which has all the advantages of the test cocks in checking the water level, but does not suffer from their disadvantages, has been patented by Messrs. Cammell Laird & Co., Ltd., and is being manufactured by Messrs. W. Crockatt and Sons, Ltd., of 64 Darnley Street, Glasgow. It consists of a perforated metal tube, and replaces the $\frac{3}{4}$-in. glass tube in an ordinary water-gauge mounting. The diameter of the holes is $\frac{1}{32}$ in. On the gauge cocks being opened, water issues from the hole below the water line in the form of a rapidly diverging white cloudy spray, well defined and readily distinguished. Steam, on the other hand, which issues from the holes above the water line, is only faintly visible and is hardly discernible. The steam jet is almost parallel and quite distinct in character from that of the water; a definite indication is therefore assured. The character of the water jet bears a distinct relation to the thickness of the wall of the tube; by reducing the thickness of the tube, the jet can be made to assume wider proportions. Good results are obtained by thinning the tube down to $\frac{1}{32}$ in. round a $\frac{1}{32}$ in. diameter hole. Much smaller holes than these, however, will give a perfectly visible jet.

PRESSURE GAUGES.

Apparatus for Testing Pressure and Vacuum Gauges.

(*Brotherhood's Patent.*)

This apparatus will test the accuracy of gauges at all steps on the scale instantaneously, independent of temperature variation, and does not rely on springs. A permanent accuracy

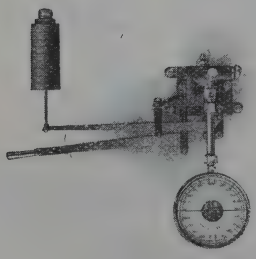

Fig. 79.

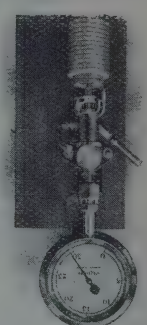

Fig. 80.

within $\frac{1}{2}$ per cent. is proved by official tests. In the pressure-gauge testing-machine a hand-operated oil pump supplies pressure below a ram which, while being entirely oil-tight under the highest pressure, will fall freely by its own weight when the pressure is released. For moderate

slowly, surely and silently the efficiency of your plant, robbing it of just that necessary power that makes THE DIFFERENCE BETWEEN PROFIT AND LOSS, and you have only yourself to blame. You can STOP THIS LOSS AT ONCE AND FOR ALL BY USING "KLINGERIT," the only jointing that has been proved under the most exacting tests to withstand high pressure, super-heat, hot oils, alkalis, acids and ammonia.

Forty years of rapid advancement in steam engineering still finds "KLINGERIT" far ahead of any other jointing for reliability and long life, a unique position that can only be maintained by rigid adherence to that quality which has made it the standard by which all other jointings are judged.

Somewhere in your plant there is need for "KLINGERIT."

Get it now and turn the "stealers" into "helping hands."

In ready cut joints or sheets, which do you prefer?

RICHARD KLINGER, LTD.

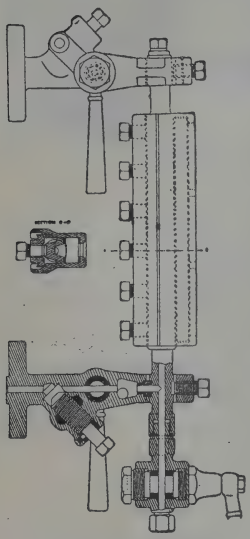
'Grams: ... KLINGPATS, BOROH, LONDON

THE STANDARD "Klingerit" JOINTING OF THE WORLD

F. 1722

KLINGER

Gauges for Water, Oil, Spirit, etc.

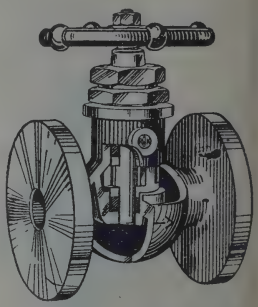


THE LATEST HIGH PRESSURE GAUGE

THE latest type is suitable for working pressures up to 1,000 lbs. per sq. inch, the great advantage of which is that it can be entirely dismantled whilst the boiler is under steam. This is made possible by the inclusion of an auxiliary plug, which can be screwed right home, thus shutting off the water and steam.

These gauges can be supplied tipped forward at an angle of 30 deg. for Babcock and Wilcox, Stirling, Vickers and Thompson water-tube boilers.

THE KLINGER "NO TROUBLE" VALVE



TESTED for over two years under the hardest working conditions met with in Power House, Factory and Engineering Works all over the country and proved to be a "no trouble" valve. *Some of the chief features:-*

NO SEAT
NO REGRINDING
NO SPINDLE STUFFING BOX

RICHARD KLINGER LTD.

120 SOUTHWARK STREET, LONDON, S.E.1.

'Phone: HOP 1384 | *Monomark:* B.C.M/KLINGER | *'Grams:* " KLINGPATS, BOROH, LONDON "

F. 1723

pressures the ram lifts graduated weights direct, and for higher pressures, up to 6,000 lbs. per sq. in., weights are applied through a lever carried on hardened steel knife edges. This is shown in fig. 79.

In the vacuum-gauge testing-machine, shown in fig. 80, an oil-sealed pump exhausts the air in the space above the plunger and below the gauge. The readings being controlled by the absolute difference of pressure within and without the gauge, no correction for barometric or temperature conditions is needed. In this respect the machine possesses great advantages compared with the mercury column often employed.

The machines can be made for fixing to the wall or to stand on a shelf or table, and are enclosed in dust-proof boxes.

A certificate of the National Physical Laboratory can be supplied with each machine.

THERMOMETERS

Negretti & Zambra's Distance Thermometer.

(Patent.)

In all superheaters and boiler work, the registration of temperature is very important, and not only should the thermometer be accurate, but it should be legible and easy to read. The instrument, fig. 81 (*Negretti & Zambra*, 38 *Holborn Viaduct*, *London*, *E.C.* 1), which is claimed to effect the desired result, is actuated by distilled and purified mercury contained in a steel bulb connected by means of steel capillary tubing to a Bourdon tube to which is attached a pointer spindle. The special feature in the apparatus is the compensation of the capillary tubing, whereby any changes of temperature of the tubing itself do not affect the accuracy of the reading; an invar wire is run down the centre of the bore of the tubing so as to make the amount of mercury in the tube to be in the same proportion to the size of the steel tube as the expansion of mercury is to the expansion of steel: thus the tubing can be made red hot and any expansion of mercury will be taken up by the tube itself. Another important feature is the construction of the Bourdon tube which enables the pointer to be attached direct to the tube itself, thus eliminating all gears, hair-springs, levers, etc.

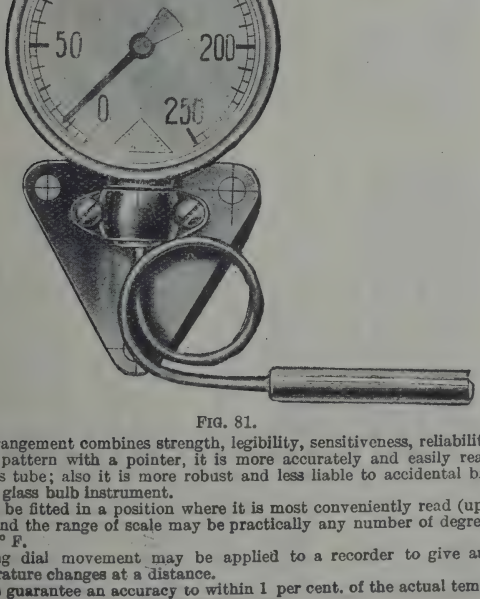


Fig. 81.

The whole arrangement combines strength, legibility, sensitiveness, reliability, and accuracy.

Being a dial pattern with a pointer, it is more accurately and easily read than a liquid column in a glass tube; also it is more robust and less liable to accidental breakages such as might occur in a glass bulb instrument.

The dial may be fitted in a position where it is most conveniently read (up to 100 ft. away from the bulb), and the range of scale may be practically any number of degrees on the dial or chart up to 1,000° F.

A transmitting dial movement may be applied to a recorder to give automatic written records of temperature changes at a distance.

The patentees guarantee an accuracy to within 1 per cent. of the actual temperature.

NOTES.—When several boilers are connected in parallel, it is most important that Hopkinson's Patent Isolating Valves, figs. 6000 and 6005, should be used.

The Steam and Feed Valve sizes are to be chosen in accordance with the evaporation and steam pressure of the boiler.

Cast-steel Junction and Feed Valves can be supplied at an extra cost if preferred, in those cases where Cast-iron Valves are specified.

Safety Valves can similarly be supplied with the parts subject to pressure in cast steel, if preferred, at an extra cost.

VALVES.

The large valves on the steam mains should each be provided with a small by-pass valve to enable a length of cold steam pipe to be warmed up, and the pressure balanced before the main valve is opened. This will prevent the straining of the joints caused by sudden expansion, and likewise accidents due to water hammer.

The outlet valve from the boiler should be at the highest point possible, so that there may be a fall from the valve towards the engine. There should not be a vertical pipe rising from the valve since this affords a pocket for water which will be dangerous should the drainage fail.

It has been suggested by W. H. Booth that since the loss of pressure in steam pipes is due to friction, there would be no very serious loss caused by a short length of less diameter placed in the course of a long pipe, and he suggests that the valves might be much smaller than the pipes, being connected to them by conical ajutages. These cones should not be isoceles but scalene, so that the floor of the valve should be in one level with the lower side of the pipe, thus allowing free flow of water. These small valves would greatly reduce the cost of the valve installation, especially where valves are numerous, as in the needlessly complicated pipe systems so much in vogue.

Stop-Valves.

The Hopkinson-Ferranti Patent Stop Valve.

This valve (fig. 82) is designed to pass an amount of steam equal to the full carrying capacity of the pipe. The working parts of the valve are similar to those of the Patent Parallel Slide Valve, and are placed in the throat of a converging-diverging nozzle. The construction allows a large reduction in size, weight, and first cost, as compared with ordinary full-way valves.

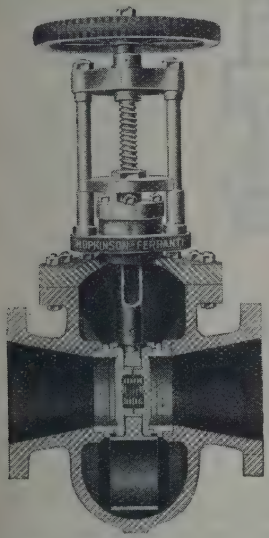

Fig. 82.

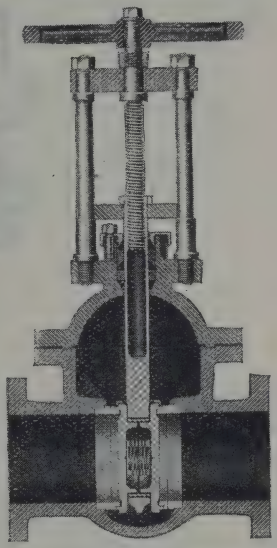

Fig. 83.

The design is such that a part of the pressure energy of the steam is converted into kinetic energy in the converging nozzle, the steam increasing in velocity and dropping in temperature and pressure. With the high velocity thus acquired the steam passes through the valve proper and enteres a diverging nozzle in which the kinetic energy is reconverted with an increase of pressure and temperature. The steam thus leaves the valve at the pressure, temperature, and velocity with which it entered the converging cone on the inlet side, the loss of pressure under normal conditions being negligible.

Hopkinson's Patent Fullbore Parallel Slide Valve.

This valve (fig. 83) is fitted with ' Platnam ' seats and discs which do not corrode or soften under high temperature of superheated or high-pressure steam.

There is no wedging action to cause unnecessary or dangerous strains or to make it difficult to open and close.

The valve when closed is held to its seat by fluid pressure and in opening and closing slides upon the seats with an equally uniform flexible pressure. The discs rotate on their axes, ensuring even wear and perfect condition of the valve faces. This valve is free from the mechanical strains usual in mushroom or wedge valves, being also fluid tight and easy to operate under varying pressures. It is fitted with Hopkinson's composite gland, which eliminates spindle gland leakage.

The Hopkinson-Ferranti Valve for steam is made in all the standard sizes from 4 inches to 24 inches diameter, with cast-iron or cast-steel body and cover in accordance with the pressure and temperature, and with ' Platnam ' disc and seats in all cases. Steam can be passed in either direction as required, the old pattern with unequal nozzles having been superseded. The principle is also applied to valves for water and air, and a number of special patterns are manufactured.

The 'Vee-Reg' Valve.

(*Engineering Specialists, Ltd., Craven House*, 121, *Kingsway, London, W.C.* 2.)

This valve, fig. 84, has a cylindrical sliding guide part (containing specially arranged triangula openings) that fits into the seat, the face of which is protected. As the valve is raised, there is no appreciable passage of steam or fluid until the faces are well apart, so when steam does pas

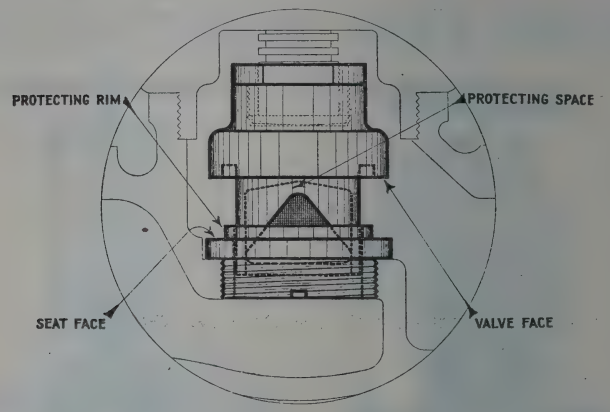

Fig. 84.

it is deflected from the faces. Thus the possibility of 'scoring' taking place is reduced to a infinitesimal degree. In addition, the triangular openings ensure a very fine control—a distinc advantage. The combination of the prevention of 'scoring' and the fine control ensures a very efficient and, incidentally, economical valve service. There are grades of these valves for al pressures from the lowest to the highest.

The Klinger Valve.

(*Richard Klinger, Ltd.*, 120, *Southwark Street, London, S.E.* 1.)

This valve (which is of quite novel design), fig. 85, consists of a piston sliding through tw flexible rings, generally of asbestos. A close contact on the piston is maintained when the ring wear, by tightening a form of gland in which the rings are held, but the rings are constructe so that no amount of pressure from this direction can displace them.

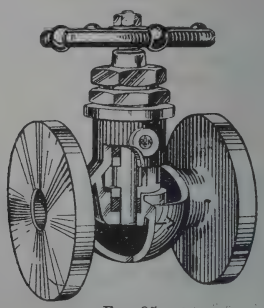

Fig. 85.

The permanent contact provided by the upper ring cuts off the working parts from the valv chest, avoids the necessity for the ordinary type of spindle stuffing box, and provides a perfectl steam-tight joint with very much less friction.

Alley & MacLellan, Ltd.
Sentinel Valve Works. WORCESTER.

The piston when lowered into and through the bottom ring closes the valve, and is of such a length that wear due to wire-drawing action takes place on the portion that protrudes, while the closing surfaces are always kept out of the steam area.

The rings have been found in actual practice to last much longer than nickel or other seatings and, of course, they are very much cheaper.

The valves are used with superheated and saturated steam, hot oils, motor spirit, water, air, gas, and chemicals, and have been found in the various materials in which they are made to be very suitable for these duties.

The principal points in favour of the valve are: extremely low maintenance costs, simplicity of adjustment, and absolute tightness under the hardest conditions.

Valve Refacers.

The Brooke Valve Refacer.

(*Patent.*)

The trouble caused by leaky valves, owing to wear or bad cutting of the surfaces, is often a source of great annoyance, and the possibility of refacing the same without removal of the valve is a very important point. This refacing can effectively be carried out by the Brooke valve seat refacer. This device (fig. 86) is very simple in all its parts, and is capable of standing a fair amount of rough usage without getting out of order, and should last the life-time of any steamer, with ordinary care.

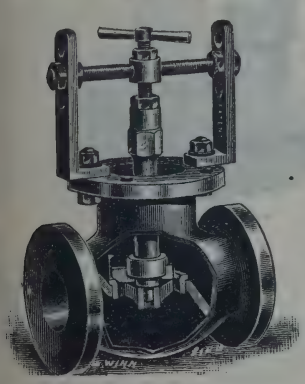

Fig. 86.

In the arrangement, the legs are reversible on the crosshead, the feet being turned inwards for small flanges, and outwards for large, also, whether fastened one way or the other, there is no part that prevents the operator from seeing the cutter. When once the machine is set in position, it need not be disturbed to change the cutter, as the mandril (which may be of any desired length) can be unscrewed from the box nut and taken out, while any extra cutters are easily made by the engineers, if required.

Disc steadies are provided for plain bore seats, and leg steadies for star-ribbed seats, which not only centre the end of the mandril at once, but obviate any tendency to vibrate—so that the machine will reface a valve-seating true, and leave it without jars or riffles.

The refacer is operated with an ordinary spanner and is made complete with five cutters and necessary guides for dealing with all sizes of valves from 1¼ in. to 4½ ins. Larger sizes are made for valves up to 10 ins. diameter.

The Simplex Patent Valve Reseating and Facing Machine.

(*W. Crockatt & Sons, Ltd., Glasgow.*)

(1)

This tool, fig. 87, has been designed to avoid the necessity of using the studs in the valve chest as a means of steadying. At the same time it is simpler and stronger than the machines which are secured and centred by means of a chuck operated by a scroll.

The tool is fixed in the valve chest (which may be either plain or screwed) by means of three stepped arms, pivoted at their upper ends. These arms are expanded by a cone which is depressed downwards by means of the hand nut. The action of expanding these arms both centres the tool in the valve and fixes it securely in position. This is ensured by the manufacture of the tool, the arms being turned up truly central with the spindle, after assembling. The cutters used are made of flat steel, and one end is arranged for flat and the other for bevelled seats. The simplicity of this type of cutter is found to counterbalance any slight advantage the milled type of cutter may have. Also a very much smaller number of cutters can be employed to deal with a large range of valves, as each cutter is adjustable. In order to prevent chattering of the tool, the feed is against the action of a strong spring, which keeps an upward pressure on the tool, so that feeding only takes place when the cutter is forced down by the action of the nut. This prevents the cutter following any irregularities in the face of the seat.

A simple attachment is provided when desired for trueing up the valves themselves. The valves are centred in this part of the tool and faced up by a movable tool, which can deal with either flat or bevelled valves. The arms and lower part of the body of the tool are made of cast steel, so that the machine will stand hard wear. Ball-bearings are fitted throughout, to ensure smooth working and to avoid jarring.

The machine is made in three standard sizes to deal with valves from $\frac{3}{4}$ in. to 8 ins. diameter, but has been supplied and can be easily adapted to do valves up to 12 ins. or more.

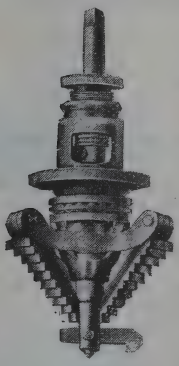

FIG. 87.

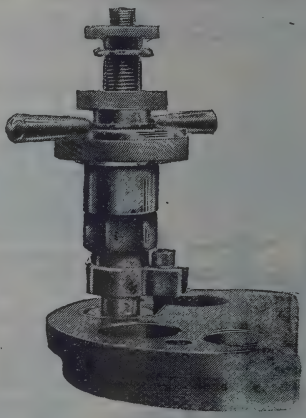

FIG. 88.

(2)

In order to meet the demand for a tool which will face up the seats of the group valves in Weir's and similar feed pumps, the Simplex No. 3 machine has been introduced. This tool, fig. 88, is secured in position by the expansion of three segments, which are turned concentric with the central spindle, and which are expanded hard against the inside of the bore of the valve seat by the action of the tapered end of the spindle. It can easily be adapted to flat or bevelled seats by simply changing the cutter used.

If it is desired to face up the valves in the bottom seat of the pump without drawing the complete seat, a special tool with an extended body can be supplied.

Besides being suitable for the type of valve mentioned, the tool is equally adaptable to dead weight safety valves, or indeed, to any design of valve in which the inside of the bore is a plain cylindrical surface. Ball bearings are fitted to ensure smooth and easy working.

REDUCING VALVES.

These are very needful fittings in connection with steam appliances when steam has to be reduced from a high to a uniform low pressure. It is a common mistake to order reducing valves too large, which leads to their excessive wear. No reducing valve should be implicitly trusted; but wherever a rise in steam-reduced pressure is liable to bring about serious results a relief valve should follow the reducing valve.

Reducing valves which are too large for the amount of steam they are to pass are usually unsatisfactory; either they will open and close continually and chatter violently, or will stand in a position nearly closed and become steam-cut and leaky. It is more satisfactory to use two small valves in parallel, one set slightly heavier than the other, so that one will supply steam up to its maximum capacity before the other opens. Another way is to use one reducing valve equal to about one-half the maximum demand, and a by-pass of about the same capacity with a hand-operated valve in it, so that when the reducing valve reaches its capacity the by-pass valve may be opened wide and the reducing valve be closed down and make up the shortage. This, of course, requires that an attendant shall observe the pressure gauge occasionally.

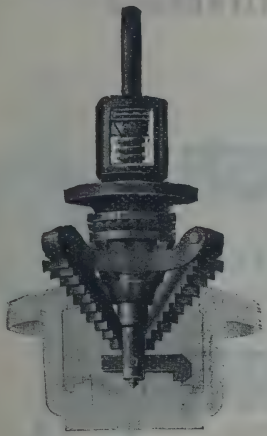
CROCKATT SIMPLEX

PATENT
VALVE RESEATER



Reduces repair costs and saves time. Enables your engineering staff to keep Steam and Check Valves tight without recourse to a lathe.

This tool has been supplied to hundreds of ships, factories, repair shops, power stations, etc., and a large proportion of our orders are repeats.

MADE IN FOUR SIZES FOR VALVES FROM ⅜" TO 12".

CROCKATT SIMPLEX TUBE BRUSHES
are made in a variety of designs for tubes from ⅜" to 27" diameter.

Among our other manufactures are
Tube Expanders, Turbine-driven Tube Cleaners, Feed Water Filters, Electric Salt Detectors, Terrazzo Floor Polishers, Machine Cut Gearing.

FEED-WATER REGULATORS.

The Crosby Patent Feed-Water Regulator.

The action of this regulator (*The Crosby Valve and Engineering Co. Ltd.*, 41–42 *Foley Street*, *London*, *W.*1) is in no way dependent upon the rising and falling of a float, and there are very few parts which are liable to give trouble and so to cause the apparatus to work in an erratic manner.

In fig. 89, A is a chamber which is put into communication with the steam space of the boiler, the steam being led in through the pipe H. A pipe L also puts the chamber in connection with the boiler, but in this case with the water space. If, for example, the apparatus is fitted to a Babcock boiler it might be placed at the side of the drum, so that the top of the chamber A is in line with the required water level. If the pipe L be then connected to the drum G, about

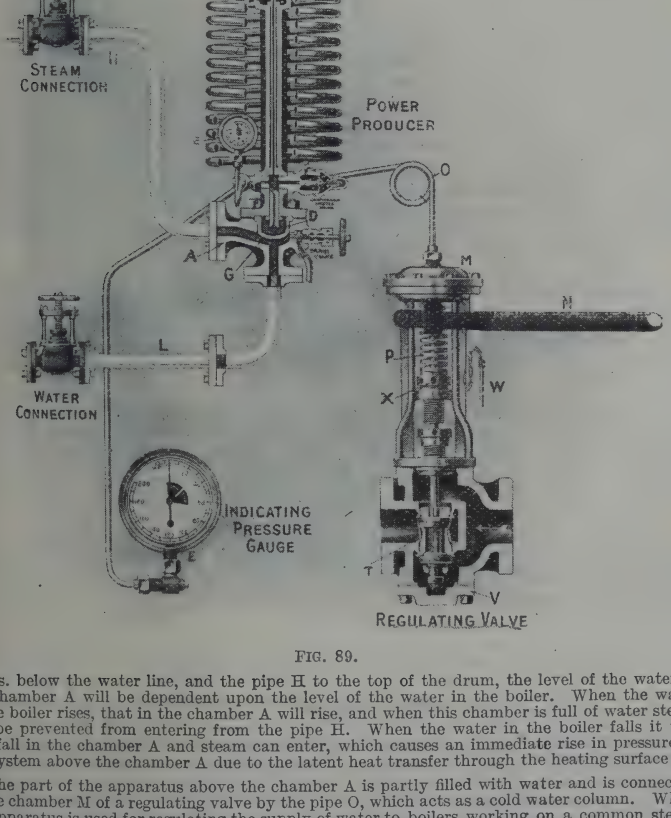

Fig. 89.

12 ins. below the water line, and the pipe H to the top of the drum, the level of the water in the chamber A will be dependent upon the level of the water in the boiler. When the water in the boiler rises, that in the chamber A will rise, and when this chamber is full of water steam will be prevented from entering from the pipe H. When the water in the boiler falls it will also fall in the chamber A and steam can enter, which causes an immediate rise in pressure in the system above the chamber A due to the latent heat transfer through the heating surface G.

The part of the apparatus above the chamber A is partly filled with water and is connected to the chamber M of a regulating valve by the pipe O, which acts as a cold water column. When the apparatus is used for regulating the supply of water to boilers working on a common steam main, the double-beat balanced valve T is connected in circuit with the feed pipe, each boiler being provided with one of these regulating valves.

There is a diaphragm in the chamber M, this being connected to the double-beat balanced valve by means of a spindle. When the water level in the boiler falls, the pressure formed in the apparatus as described below is exerted on the diaphragm, causing the valve to open against the action of the spring. When, however, the water rises, this pressure falls and the spring causes the valve to close, thus shutting off the supply of water to the boiler.

When the apparatus is first put into use, both the cocks on the boiler are closed, so that neither steam nor water can enter the chamber A. The air valve B is removed, and water is poured in. At the same time the union, or plug, on the diaphragm chamber is loosened, in order to enable the water to drive out the air in the pipe connecting the two pieces of apparatus. This having been done, the union on the chamber M is again tightened up, and more water is poured into the chamber at B when the air valve is closed. Steam from the boiler is then admitted under the partition G and the water in the system above is boiled up, the air valve B being loosened to let the air escape. This process is repeated several times, and on each occasion the apparatus is allowed to cool. In this way a vacuum is created in the apparatus above the partition G, and when a gauge to the left of the upper chamber registers a vacuum of at least 10 ins. the device is ready for use. The gauge serves for registering both pressure and vacuum, the latter being to the left of the zero mark and the former to the right of it.

The vacuum having been obtained, the two cocks on the boiler are opened, and the device commences to work. When the water in the boiler falls and steam is admitted to the chamber A through the pipe H, the heat of the steam is transmitted through the plate G. This heat boils the water in the chamber D. The pressure of the steam so generated, acting on the surface of the water in the top chamber, gives rise to a pressure above the diaphragm in the chamber M. This diaphragm is depressed, and the valve (which in a battery of boilers is arranged in the feed-pipe to each boiler) is opened, a supply of feed-water is admitted to the boiler, and in this way the water level is raised. As the water rises in the drum of the boiler, it also rises in the chamber A, and when the proper level in the boiler has been reached, steam ceases to enter from H. The chamber A then contains nothing but water. Under these conditions the water in the chamber D is no longer evaporated, and the steam condenses, the pressure in the top chamber consequently falls, and the valve closes. The supply to this particular boiler then ceases for the time being. The pressure gauge indicates whether the apparatus is working properly, and in this way the stoker is provided with a means of guarding against low water even should the device get out of order, which, however, is not at all likely to occur.

When the apparatus is working properly the pressure rises and falls slightly in accordance with the fluctuations in level in the boiler, opening the regulating valve wider or allowing it to close, thus increasing or reducing the feed supply to the boiler. It does not constantly open and shut, but regulates the feed so as to keep the water level constant within close limits. A lever is provided on the regulating valve for testing its operation or to keep the valve open if desired, and an adjustable device is provided to keep the valve always open a limited amount if required.

The principal advantages claimed for the apparatus are the following:—(1) It enables a lower water level to be maintained with perfect safety, thus increasing the steam space in the boiler and ensuring a supply of dry steam; (2) it reduces coal consumption by reason of maintaining a regular feed proportionate to the evaporation of the boiler; and (3) it ensures a greater regularity in the steam-raising, and so tends to prevent fluctuations in the pressure; (4) it will work continuously without requiring attention or repair.

A desirable adjunct to the Boiler Feed Regulator is the Crosby Automatic Feed Pump Control. This regulates the speed of the Boiler Feed Pump in accordance with the demands of the feed line to the boilers; and consists of a balanced valve in the steam supply pipe to the pump, controlled by means of a device which maintains the pressure in the feed line a constant amount above the boiler pressure irrespective of the demand. The magnitude of this excess pressure is adjustable at will.

The 'Drayton' Feed-Water Regulator.

(The Drayton Regulator & Instrument Co., Ltd., West Drayton.)

This regulator, fig. 90, is of the 'delayed action' thermostatic type, the lag of the thermostat allowing the stoker to adapt the firing to altered conditions of steam consumption. The all-metal thermostat is contained in a steel tube which lies at an angle outside the boiler across the normal water-level line; the highest point of the tube corresponding to the highest, the lowest point to the lowest permissible water level. The upper end of the thermostat container is connected to the steam space, the lower end to the water space of the boiler. The thermostat actuates through a magnifying lever a small relief valve, which latter is connected to the

pressure chamber of the feed valve, into which water enters at 15 lbs. per square inch pressure through a strainer and a needle valve. With rising water level the thermostat contracts, closes the relief valve, and allows the feed valve to close; with falling water the tube fills

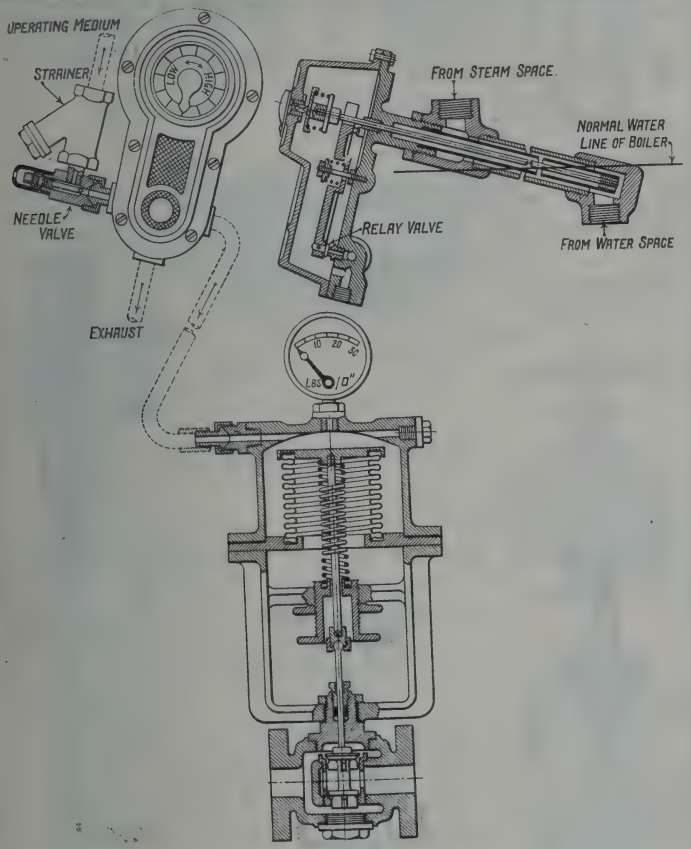

FIG. 90.

with steam, the thermostat expands, opens the relief valve, and causes the feed valve to open gradually.

THE 'THERMOFEED' FEED-WATER REGULATOR.
(Patent.)

This regulator consists of a float chamber and an automatic regulating valve.

Fig. 91 shows how the appliances should be fitted to the boiler front. This can be effected either in the way shown, or connection may be made behind the gauge glass, using the suitable pieces. The chief point is to provide steam and water connections from the boiler to the float chamber.

In the float chamber is a float made of special material, and guaranteed non-collapsible under any reasonable pressures. By a system of toggles the motion of the float is transmitted to a

small valve, which will either stop or allow steam to pass through a three-way valve to the large automatic regulating feed valve fitted into the feed supply pipe of the boilers. As long as sufficient water is in the boiler—*i.e.* the float being at a certain height—no steam is allowed to pass to the regulating valve; but if the ball rises to a certain point, steam connection is made, the steam condenses and reaches the piston on the top of the regulating valve, so that a certain

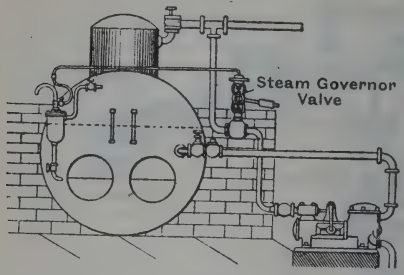

FIG. 91.

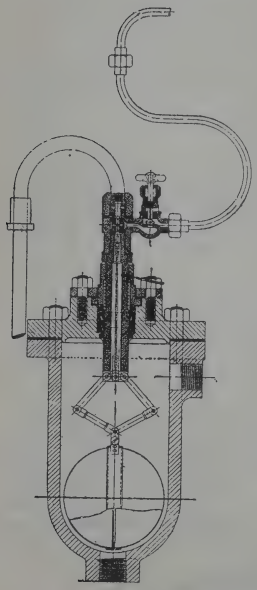

FIG. 92.

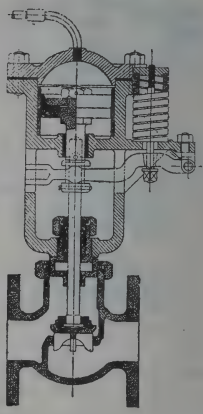

FIG. 93.

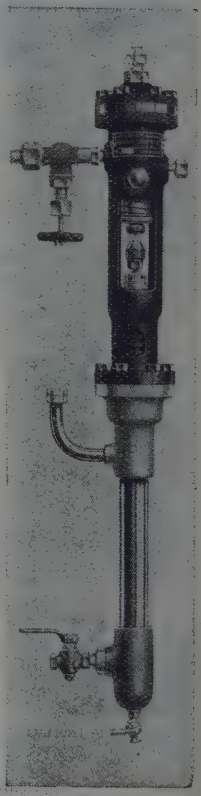

FIG. 94.

head of water is resting upon it; this will cause the feed valve to close and will prevent any more water from entering the boiler. If the water becomes lower, the float drops; the steam then passes through to the exhaust tube (shown as a slight bend in the fig.), and the automatic regulating valve opens again to admit water.

A special and distinctive feature of the Thermofeed is that by closing the three-way valve on the float chamber the regulating valve is always full open; hand feeding may therefore be resorted to at any time if constant heavy alterations in the load occur.

THE

"BAKER"

OIL

SEPARATOR

FOR EXHAUST STEAM

(*See Editorial Notice p.1736*)

Sole Makers

The BAKER OIL SEPARATOR Co.

MELROSE STREET WORKS - - - SCARBOROUGH

The same principle of feed-water regulation is also used for marine purposes, but certain modifications have been made. The float is guided in such a manner that the rolling of the ship is unable to influence this unit, and the design is modified in order to meet general marine conditions.

In a single boiler installation the Thermofeed regulator may be used to start and stop the pump automatically. As will be seen from figs. 92, 93, this is possible by providing a special type of governor valve in the steam supply pipe to the pump, this governor valve being connected to the float chamber as shown. It will be understood that the admission or cut-off of the steam results in the pump being started or stopped.

The arrangement will maintain the water-level within a variation of $\frac{1}{8}$ in. (water-tube $\frac{1}{4}$ in.), acting independently of the pressure of the steam or the temperature of the feed.

By the use of the regulator a saving of 8 per cent. in coal bills is stated to be not unusual.

The manufacturers also supply a Differential Governor (fig. 94) for use in conjunction with the Regulator or independently on any self-starting steam pump. The pump governor automatically starts the pump and stops it if excess pressure is created in the feed supply pipe. The waste of bye-passing the not required water is, therefore, obviated, and the governor is a power saver of the first order.

The pump governor consists of a cylinder which is connected to the water and steam supply as indicated above. The water presses on a glass ram which acts on a small controlling valve. This small controlling valve acts in its turn on a stop valve built into the steam supp y of the pump. It is obvious, therefore, that at a pre-determined pressure the pump is stopped or started again as soon as the pressure in the water line falls. The 'Thermofeed' pump governor can be adjusted for any desired ranges of pressure.

The 'Arca' Compact Valve.

This valve (fig. 95) is used for small steam, air, or water regulating valves where the hydraulic

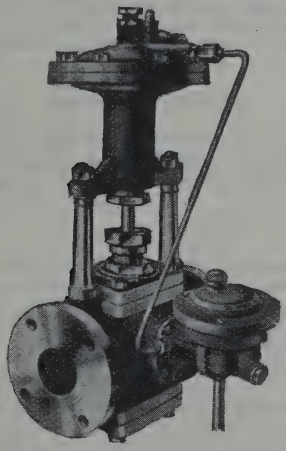

Fig. 95.

cylinder is unnecessary and where only comparatively small power is required to operate the valve; it is operated by a diaphragm in precisely the same manner as the pilot valve is operated where a hydraulic cylinder is used. Great care has been taken in the design to ensure the same accuracy and reliability as with the cylinder type. The cost of the combined unit embodying relay and compact valve, is of course considerably less than the cylinder type, though possessing the same sensitiveness and accuracy. It is particularly suitable for use with steam for heating purposes.

OIL SEPARATORS.

Lubricating oil, if allowed to pass into boiler feed-water, constitutes a danger to boilers so serious that means for its separation and removal are now invariably insisted upon by insurance companies. The method generally employed is that of the mechanical separation and extraction of oil and grease from the exhaust steam before it enters the condenser.

The fitting of high-pressure boilers with superheaters has increased the difficulty of the removal of the oil, while rendering the necessity of the complete separation all the more imperative.

For *small* quantities of greasy water, finely-broken coke placed in a perforated-bottom pail and hung below the greasy drip of an exhaust pipe has been found efficient in separating oil.

The 'Baker' Patent Oil Separator for Exhaust Steam.

(The Baker Oil Separator Co., Scarborough.)

This separator is designed to eliminate lubricating oil from the exhaust steam of all classes of reciprocating engines and under all working conditions, varying between 29 inches of vacuum and 75 lbs. per square inch back pressure. The sizes made have pipe connections ranging from 2-in. bore to 60-in. bore. Separation is effected by mechanical means only, the apparatus being fitted into the exhaust steam pipe between the cylinder of the engine and the condenser or other receptacle in which the cleansed steam is to be used. The makers give a definite guarantee as to the results obtained, which in actual practice means that all condensed steam can be used for boiler feeding, or any manufacturing purpose, without fear of oil contamination. The apparatus is extensively used for colliery winding, rolling mill, and central exhaust engines, special attention being given to the strength and rigidity of all internal parts, to ensure their withstanding the heavy pulsations from these types of engines. In every instance, each Baker Patent Oil Separator is designed and manufactured to suit the particular working conditions specified at time of ordering, and is guaranteed accordingly. It should be noted that the makers' claim is to cleanse the exhaust steam, not to recover the lubricating oil, although in many of the larger installations as much as from 50 per cent. to 75 per cent. of the oil is recoverable for use again.

There are no maintenance costs in running the apparatus.

The 'Drayton' Oil Separator.

(The Drayton Regulator & Instrument Co., Ltd., West Drayton.)

This separator differs from other types by the absence of rigid baffles. The eliminators consist of vibrating elements which shake off the oil into an inverted cone-shaped bottom, from where it is removed in the usual way by grease trap or vacuum trap of the makers' own design.

It is claimed that one-tenth of a grain of oil per gallon of condense can be guaranteed without time limit.

BOILER CLEANERS.

The Hulburd Mechanical Boiler Cleaner.

Excellent results have been obtained with the Hulburd mechanical boiler cleaners, apparatus which, although suitable for all classes of boilers, are especially recommended for locomotives, in

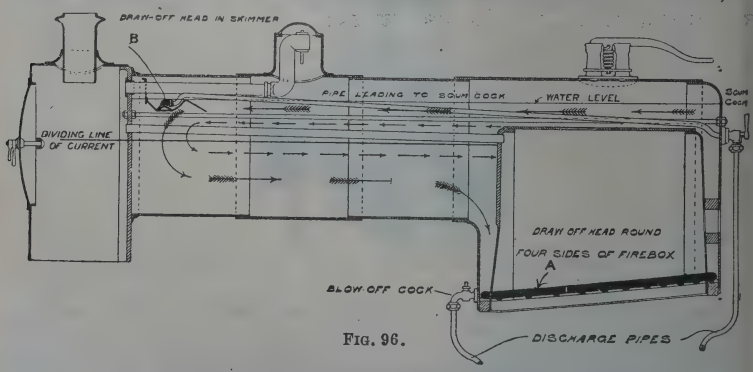

FIG. 96.

which reduced efficiency of the heating surfaces, due to formation of scale and obstruction of the water spaces by accumulations of deposit, are above all things to be prevented if possible.

As almost invariably fitted, the cleaners, fig. 96, consist essentially of two portions; one in

the boiler barrel, placed in such a position near the forward end as to collect all scum-forming matter in a kind of skimmer-trough, or basin, to which it is brought by the natural circulation of the water and from which it is discharged, while running, by a suitable cock worked from the cab ; the other in the water spaces surrounding the firebox, immediately above the foundation ring, to evacuate by means of blow-off cocks the sediment which otherwise inevitably accumulates there. Both front and back portions are in the form of draw-off heads having openings or suckers on their undersides spaced so as effectively to scour the whole of the surfaces with which they have to deal, and their efficacy is such that an engine fitted with the apparatus, working on water which may previously have necessitated opening up the boiler and washing out every four or five *days*, can with the Hulburd cleaners be run 5, 6, or even 8 *weeks* without being laid off a single day for cleaning in the ordinary sense.

Among the advantages obtained by the use of the cleaners are :—

1. The immediate stopping of priming by the use of the scum cock in connection with the forward fitting.

2. The preservation of the boiler tubes, firebox sheets, stays, etc., in a clean condition through the removal of all scale-forming matter as soon as it is deposited. The cleaners' action may be advantageously assisted in some cases by the use of a suitable boiler composition, which together with other resultant solid matter is evacuated as soon as it becomes inert.

3. Immunity from leaky tubes, stays, and strained tube plates, owing to the less frequent necessity for cooling down and washing out boilers.

4. Saving in washers' wages, cost of repairs, and depreciation of boiler fabric.

5. More efficient steaming, owing to the entire boiler being kept clean, and a consequent saving of fuel.

Soot Removers.

It has been shown that the presence of scale on the water side of boiler heating surfaces does not affect the efficiency very much. The presence of ' soot ' on the gas side, however, is more serious in this respect. The provision of efficient soot removers is therefore of importance.

Some modern installations are provided with permanent pipe connections, valves, and nozzles, so that jets of steam may be directed on the boiler tubes in order to remove the soot by merely operating the valves.

The Willcox-Ramoneur Boiler-Tube Soot Remover.

This apparatus, fig. 97 (*W. H. Willcox & Co. Ltd.*), consists of a 10-foot length of specially-constructed flexible Trellis Metal tubing, attached to the following parts :—*For Smoke Tubes*: a specially-designed, cone-shaped head, made in either of three sizes, viz. :—*large*—to suit tubes above 2¾-in. bore ; *small*—to suit tubes up to 2¾-in. bore; *extra small*—for loco. tubes ; this cone head is provided with an internal interchangeable nozzle, spiral partitions or webs, and a disc throttle for regulating the admission of air. Steam lance of finest quality steel tube. A sliding hand-hold, also protector on handling end of tubing. Lever regulating valve. Steam valve for fixing to steam pipe on boiler.

A special type is made for locomotives fitted with superheaters. This superheater type is arranged for cleaning both the fire tubes and the superheater tubes from the fire-box end, and is supplied with various cranked lances to reach the nest of tubes. For water tubes a slightly different pattern (for blowing around the outside of the tubes) is supplied.

The boiler being cleaned utilises its own steam—it does not have to be shut down.

The action of the apparatus is as follows :—On the steam valve being opened the steam passes through the flexible tube into the nozzle. This nozzle is made in various styles to suit the type of boiler and the existing steam pressure. Passing from the end of this nozzle, the steam meets with ten times its own volume of hot air drawn in from the surrounding flues of the boiler, and is thoroughly mixed with same. The combined hot air and steam strike against spiral-shaped partition webs inside the cone head, and, by the united action of the nozzle and the partitions, emerge at an increased velocity through the mouth of the cone into the boiler tubes in spiral form. The steam at this point has become completely dried by the admixture of hot air, and, further, it is now joined by an additional current of warm air from the exterior of the cone ; the whole ærated mass then assumes what is best described as a ' whirlwind ' movement, which sweeps with great force through the boiler tube, and drives all deposits out at the opposite end, in a similar manner to that of a projectile from a gun. As the steam is thoroughly dried in the process, there is no coagulation, and formation of sooty incrustations is avoided.

In the water-tube pattern the apparatus is fitted with a tubular end-piece, joined at its base to the form of cone head shown. The opening at the tubular end is provided with a spreader which creates a fan-shaped spray, which is directed upon the outside of the water-tubes. With

this arrangement it is possible to sweep away thoroughly, and with equal velocity, the soot and ash dust which collect on the surfaces of these tubes.

For works using both types of boilers the *'Combined Ramoneur'* is supplied. This is arranged with interchangeable heads, so that either the smoke or water-tube pattern may be utilised as required.

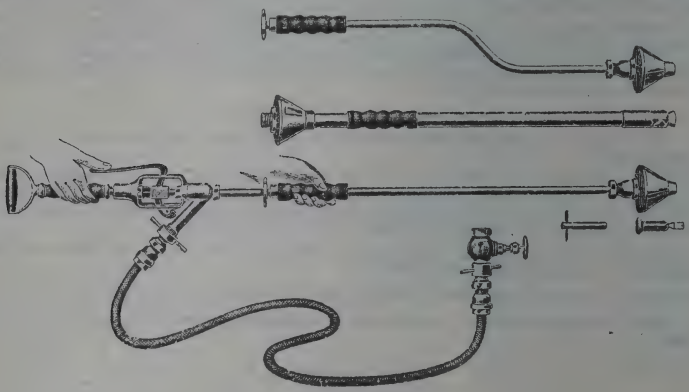

FIG. 97.

TUBE CLEANERS.

SIMPLEX PATENT BOILER TUBE BRUSHES AND SCRAPERS.

(W. Crockatt & Sons, Ltd., Glasgow.)

The 'Simplex Boiler Tube Brushes' are made with short hardened steel wires which, being comparatively unyielding, are capable of removing deposits which softer brushes will not readily attack. The necessary spring of the brushes is obtained through the action of the arms, which are made of spring steel of sufficient strength to put a reasonable pressure on the tubes being cleaned. The filling of the brush plates is done in a special machine, and in such a way that it is impossible for the bristles to come out, unless they are worn quite away.

Two designs of brush are made, the 'Self-Adjusting Brush,' which depends for its action entirely on the spring of the arms, and the 'Adjustable Brush,' which also has a certain amount of spring in the arms, but which has also a central spindle with a wing nut at each end, by which the diameter of the brush can be increased within a limited range.

The 'Simplex Patent Tube Scraper' is made of drop forgings and will remove harder deposits than will the brushes. It is arranged to scrape only on withdrawal from the tubes, so that the soot, etc., is brought to the front of the boiler, and not shoved into the back ends. This tool also is adjustable by means of a nut which is easily operated as required.

The 'Simplex Condenser Brushes and Scrapers' are for use in marine work as well as on shore.

THE CROCKATT SIMPLEX TURBINE TUBE CLEANER.

(W. Crockatt & Sons, Ltd., Glasgow.)

This appliance (fig. 98) is made in sizes from 1⅜ ins. upwards, and is driven by a turbine suitable for either air, steam, or water, at about 100 lbs. pressure. The cleaning head is detach-

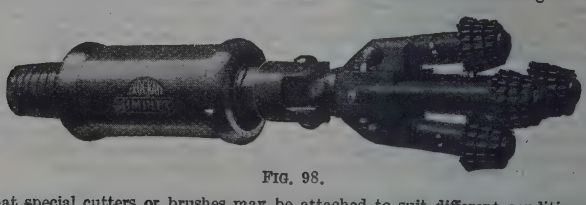

FIG. 98.

able, so that special cutters or brushes may be attached to suit different conditions, and the universal joint enables the tool to be used in curved tubes, such as in Stirling boilers. It is suitable also for Babcock tubes, economiser tubes, and any other kind of pipes having hard scale.

STEAM PIPES.

It is essential in steam pipe arrangements to make adequate provision for (*a*) drainage, and (*b*) expansion.

The pipes if possible should not rise from the valve on the boiler to the main steam pipe, as this causes a dangerous water pocket and, if suitably drained, only automatic steam traps should be used; these should be tested by blowing to atmosphere at least twice a day.

The best steam pipe arrangement between engine and boiler is that the boiler stop valve should stand at the top of a vertical pipe on the boiler and there should be a steady, if small, slope from that valve to the engine separator. Rupture from water-hammer occurs from failure of pipe drains, and if possible all drains should be unnecessary by design. The closing of no valve should be able to cause water to accumulate against it. Where it is impossible to avoid drainage points, these should be carefully arranged, and unduly small drain pipes must be avoided lest they choke with rust or dirt. New pipes and drains especially should be well blown through before fixing traps.

Long lengths of drain piping, from steam mains to traps, should be avoided; they are a continual source of waste, and with superheated steam the water they drain away has largely been formed by condensation in the drain piping itself. Therefore the pipes from steam main to traps should be as efficiently lagged as the main steam line.

Idle parts of the steam range should be isolated when not in use, and carefully drained, as valves often leak when shut, through scoring of faces and grit wedging in, preventing tight closing.

All live steam drains should be returned to the feed tanks.

(See also Manchester Steam Users Association Reports 1907, 1908.)

The connecting pipes from the boilers to the main steam pipe, and from the main steam pipe to the engines, should be preferably of steel, with half (not 'full,' which would form a 'water pocket') swan-neck bends, to allow for expansion.

Steam pipes between 32° and 212° F. expand by heat 0·0000111 per degree C. = 0·00000618 per degree F., if of cast iron. For wrought iron these figures become 0·0000118 and 0·00000656. Between 60° F. and a pressure of 190 lbs. or a temperature of 383° F. the expansion is about 4½ ins. per 100 ft. The coefficient for steel is 0·000006 per degree F.

With superheated steam, pipes may expand nearly 6½ ins. per 100 ft. of their length. At higher temperatures the coefficient of expansion is considerably larger.

In fixing pipes the expected movement when hot should, if possible, be half provided for in the opposite direction, in order to minimise stresses.

Expansion bends are best arranged to project horizontally from the line of pipe, in order to allow a free passage for water. If they stand vertically upwards they prevent water flowing, and if hung downwards they form water pockets. In both cases they necessitate careful drainage.

Pipes often vibrate under the pulsating demand of steam by an engine. This requires that they should be anchored at one or more points.

The pipes should be marked when cold opposite marks on the walls, and again when hot. Anchors should be at the points where least movement is shown. Pipes are best carried on brackets. Where they rest they should have rubbing pieces firmly attached, and they should not rest on rollers as the friction helps to check vibration.

The centre of a main steam pipe should be anchored, to divide the longitudinal expansion. Where engine and boiler room are in line and steam mains are of considerable length, a ∩ or Ω-shaped bend should be inserted between the engine and boiler-room. Anchor-plates should then be fixed in the centre of the engine-room main and in centre of boiler-room main.

When erecting new steam pipes, attention should be given to the thorough cleaning of the pipes, as otherwise fine particles of grit, driven by the steam into the faces of the valves, cut into the seats, causing considerable trouble and expense.

Riveted pipes and flanges may be used from 6 ins. diameter upwards.

If the pipes are of riveted steel the necessary thickness must be secured for caulking. It is not the practice to make these plates less than ¼-inch; it is better to use $\frac{5}{16}$ plates. To avoid risk of rivet-heads springing off during caulking, rivets should not be less than $\frac{5}{8}$ in. in diameter.

Serviceable and reliable steam pipes may be made up of lap-welded mild steel with heavy wrought-iron flanges, the flanges being screwed on hot and the ends brazed. The flanges must be faced up to enable good joints to be made.

The radius of curvature measured to the centre of pipes should not be less in solid drawn pipes than three times the diameter of pipe; even this radius of curvature causes a reduction in thickness of 20 to 25 per cent. on the outside of the bend, and a corresponding increase in thickness on the inside. Sharper bends can, if necessary, be made by working the pipes out of two plates with a brazed joint along each side. The latter construction is more expensive than the former.

STANDARD RADIUS OF STEEL AND WROUGHT-IRON STEAM PIPE BENDS.

Bore .	Ins. 1½	Ins. 2	Ins. 3	Ins. 4	Ins. 5	Ins. 6	Ins. 7	Ins. 8	Ins. 9	Ins. 10	Ins. 11	Ins. 12
Radius	Ins. 6	Ins. 9	Ft. 1	Ft. Ins. 1 3	Ft. Ins. 1 6	Ft. Ins. 1 9	Ft. 2	Ft. Ins. 2 6	Ft. 3	Ft. Ins. 3 6	Ft. 4	Ft. Ins. 4 6

Radius may be slightly less, but this is not advisable.

Pipes may be best bent by filling with thoroughly dry sand and plugging the ends. They will then bend without buckling.

Copper pipes are bent by being filled with melted resin, or with solder, the pipe bent cold, and the filling then melted out.

Copper pipes (although not advisable), if used for steam, should be solid drawn, and not brazed. Flanges to be screwed and brazed should be of brass in all cases. On no account should copper or brass be used for superheated steam, owing to loss of strength at these high temperatures, which to obtain the full benefit of superheat is raised to 650° or 700° F. (*Horobin.*)

Brazed copper is apt to be unreliable, and copper steam pipes ought to be wound with steel wire.

Corrugated Steel Steam Pipe Bends.*

These bends, which are adapted for resisting steam at a pressure of 400 lbs. per sq. in. superheated to a temperature of 750° F., have a series of corrugations (fig. 98A) which in themselves strengthen the tube, especially as the process of manufacture thickens the wall of the tube. The corrugated pipe is formed into a bend in the usual way, and there can be no thinning of the wall in bending as all that happens is that the corrugations are somewhat opened out on the outside of the bend and are closed up on the inside.

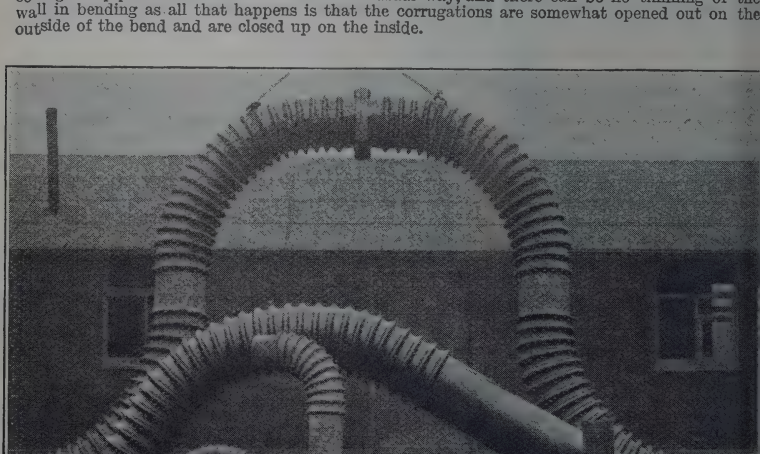

Fig. 98A.

These corrugated pipes can be bent to a much smaller radius than plain pipe—in extreme cases they can be bent to the same radius as an elbow. In all cases, to stand corrugating, the tubes must be of a good soft quality of steel and must be well made, free from variations of thickness; they are usually solid drawn tubes, hot finish, 24 tons to 28 tons tensile, 25 per cent. elongation in 8 ins.

Bends made from corrugated tube are five times as flexible as similar bends made from plain tube—that is to say, if the same thrust is applied to both bends the corrugated one will move five times as far as the plain one.

An expansion bend of the lyre type made from plain tube 10 ins. bore and 138 ins. high from the centre of the main to the centre of the pipe at the crown of the bend, allows for a movement

* 'Steam Pipes for Extra High Pressure and Temperature,' paper by J. A. Aiton, C.B.E. (*Transactions of the Institute of Marine Engineers*, Oct. 1926).

of 2½ ins. out or in; a bend made from corrugated pipe of the same bore can be made 55 ins. high, and gives 2½ ins. out or in, and a similar bend 72 ins. high gives 3⅜ ins. out or in, or 50 per cent. more than the much larger plain bend.

The severest test of the behaviour of the bends under heavy vibration has been on steam hammers. A 5-ton hammer when first started to work had connected to it a plain 5-in. steel bend and subsequently a copper bend, but this did not last more than a month, and the steam joints had to be remade, on an average, once a day. A 5-in. corrugated bend 24 ins. × 20 ins. made from stock solid-drawn hot-finish tube, $\frac{7}{32}$ in. thick, was fitted, and after working for two years was microscopically examined and showed no signs of deterioration.

Roughly speaking, the pitch of the corrugations is 2½ ins. and each curve of the corrugation 1¼ ins. The steam friction is about double that of a plain bend.

There are no records of a corrugated pipe ever having failed in service.

Pipe Thickness.

If t = thickness in inches; p = pressure in lbs. per sq. in.; d = internal diameter in inches.

$= \frac{pd}{6000}$, for lap-welded iron or lap-welded or solid-drawn steel, provided the thickness is not less than ¼ in.; $t = \frac{pd}{3500} + \frac{1}{4}''$, for cast iron;

$t = \frac{pd}{6000} + \frac{1}{16}''$, for brazed copper; $t = \frac{pd}{6000} + \frac{1}{32}''$, for solid drawn copper

(*Philip Dawson.*)

Lloyd's Rules for Steam Pipes.

The following is abstracted and abridged from Lloyd's Rules:

Pipes made from electro-deposition of copper on a mandril are not to be used for steam.

Copper pipes are to be properly annealed.

Copper pipes for pressures over 75 lbs. per square inch are to be solid drawn.

Pipes for pressures above 180 lbs. per square inch are not to be of copper if the diameter exceeds 5 ins.

Copper pipes are not to be used for superheated steam.
Permissible working pressures (W.P.) are as follows:

where,

t = thickness in hundredths of an inch; d = diameter of pipe in inches.

For brazed copper . . . . . W.P. $= \frac{45\,(t-3)}{d}$

For solid-drawn copper . . . . . W.P. $= \frac{60\,(t-3)}{d}$

For solid-drawn cold-finished steel . . . W.P. $= \frac{120\,(t-10)}{d}$

For solid-drawn hot-finished steel . . . W.P. $= \frac{120\,(t-12)}{d}$

For lap-welded iron or steel with or without covering straps . . . . . W.P. $= \frac{90\,(t-12)}{d}$

Pipe Hangers.

Exhaust Pipes.

These may be of cast iron and should be free from blow holes. The flanges should be faced and jointed with soft rubber rings. Exhaust pipes should be painted while under vacuum, preferably with several coats of red lead paint well brushed in until all the pores are filled. It has been suggested that exhaust pipes, especially if long, might be laid in a concrete trench under water so as effectually to prevent air leakage.

Flanges and Joints for Steam Pipes.

Pipes for steam and hot water should not be jointed with socket and spigot; this is a dangerous type of joint.

Steam pipes may be screwed into sleeves or branch pieces, but the screws should be tapered. This method is quite good for small-bore pipes which do not have to stand up to a very high steam pressure, and seems to have been adopted generally by American engineers for marine work. It makes a very neat job and is easy to cover.

Flanges should have the number of bolts increasing in multiples of 2. In marine work the usual method for spacing the bolts with regard to position of flange is as follows: For vertical and inclined flanges there should be one bolt hole spaced on either side of vertical centre line, and for horizontal flanges one bolt hole spaced on either side of fore and aft centre line of flange. The thickness of flanges for different materials to some extent should vary with the modulus of elasticity of the material, and consideration given as to shock and vibration which may take place.

The following formula gives thickness of flange with the constants as now generally adopted by the British Engineering Standards Association for marine flanges:—

$$\sqrt{\frac{4P \times l^4}{t^3}} = \text{constant } (C).$$

C for cast iron = 11; for brass or steel = 12·5 to 13·5,

where,

P = working pressure in lbs. per sq. in.; t = thickness of flange in ins.; l = pitch between bolts or studs.

For the attachment of flanges to pipes up to 8-in. bore, the usual practice is to screw on the flanges with a vanishing thread, which should be about 11 threads per inch. These screwed-on flanges require to have collars in order to obtain a suitable depth of screw, which varies from $1\frac{1}{8}$ in. to $1\frac{1}{2}$ in. For pipes above 8-in. bore, the flanges are riveted on.

For steam pressures up to about 180 lbs. per sq. in., machine-faced flanges may be jointed simply with a ring of copper, preferably corrugated, or jointed with some form of asbestos, such as Kymbala or Tauril jointing.

In large-sized steam pipes, also small pipes for high-pressure and superheated steam, it will be found that the best joints are made by forming a channel recess round face of flange $\frac{1}{16}$ in. deep and $\frac{1}{4}$ in. wider than the diameter of bolt holes. The face of the flange projecting above this recess is scraped up by hand to suit a small hand surface plate. The channel is then filled with red lead paint or some type of soft asbestos packing, when making up joint. This form of joint is adopted universally for high-pressure steam from about 200 lbs. per sq. in. and upwards.

A cement for pipe joints that is said to be as good as red lead putty in a faced or rough flange joint, but at one-tenth the cost, consists of a mixture of ordinary pine tar and dry oxide of iron. It is stated that it does not harden so soon as red lead, and is very adhesive under pressure.

A thin gasket has less edge surface exposed to the pressure, and is therefore less likely to blow out than a thick one.

The Use of Metallic Gaskets.

The ordinary corrugated copper gaskets are approximately $\frac{1}{64}$ in. thick, and are generally used as a ring inside the bolt circle.

Some engineers recommend the use of two gaskets in order to allow for the spring of the pipe flanges when bolted up. Flanges, however, should be stiff enough not to spring sufficiently to touch at the edges when one gasket is used. The second gasket should then be omitted. The gaskets should be dipped in jointing red lead (red lead mixed with boiled oil). Metal gaskets should be coated with pipe cement, graphite and oil, or lead and oil, and bolted up before the coating has dried, so that each corrugation flattening under the pressure forces a ring of this filler concentrically around the flange, and the copper gasket practically acts as a binder. Copper gaskets should be annealed soft and pliable after corrugating.

The ideal gasket is one that covers the pipe ends as well as the flange if the pipes are faced off flush with the flange, because such a gasket will save thread leaks. If, however, the pipe does not come out flush with the flange, this cannot be accomplished with any gasket.

For jointing purposes the corrugated copper gaskets in common use have not been very successful with superheated steam. The reason lies in the fact that the annealing temperature of copper lies in the neighbourhood of 600° F., corresponding with a boiler pressure of 180 lbs. to a superheat of 220°. Corrugated gaskets, moreover, used by careless pipe fitters are always likely to give trouble owing to the danger of the bolts and flanges being overstrained. Joints of asbestos and of rubber preparations have often been used, but they last but a short time. It is fairly certain that the high temperature of superheated steam at the usual boiler pressure prohibits the use of organic material for jointing purposes if results of any permanence are desired. A satisfactory joint has been found to be one in which a gasket of thin steel of a radial width not exceeding $\frac{5}{8}$ in. has been used, the steel being soft annealed. The comparatively small area of the gasket enables great pressure to be brought to bear by bolts of ordinary size, with the result that the soft steel is thoroughly pressed into the rough surface of the flange. Such a joint will, although simple and cheap, give all the permanence that could be desired.

(*Times Engineering Supplement.*)

'Dexine.'

This material (*Dexine, Ltd.*) is a very suitable substance for making joints. It does not stick to the flanges, nor does it press out, blow out, or burn out; and it can be used over and over again. It is made in sheets from $\frac{1}{64}$th inch upwards.

Beldam's Pilot Jointing.

(*The Beldam Packing & Rubber Co., Ltd.*, 16 *Gracechurch Street, London, E.C.*3.)

This is a compressed asbestos fibre jointing for all steam or water pressures, ammonia, acids, oils, etc. It will stand temperatures (up to 750° F.), and will not burn, blow, or squeeze out. Its tensile strength is over 3 tons per sq. in.

Joints made of this material can be opened up as often as desired, and it does not lose its elasticity.

To facilitate quick measuring when cutting, the sheets are marked in 1-in. squares.

Leaks in Steam Pipes.

Leaks in steam pipes that cannot be stopped by caulking or plugging may be stopped with a cement made by mixing black oxide of manganese with enough raw linseed oil to form a thick paste. The steam pressure should be relieved in the pipe, but the pipe should be kept warm enough to dry the oil.

Size of Steam Pipes.

The diameter of a steam pipe is usually in practice chosen to give a certain steam velocity in the pipe, 100 feet per sec. being a customary velocity for steam at ordinary pressures.

Many engineers use this speed for both saturated and superheated steam. Others vary the velocity as in the following table:

Diameter of Pipe.	Velocity. Feet per sec. Saturated.	Superheated.
Up to 3 ins.	75	100
3½ ins. to 9 ins.	90	120
10 ins. and over	90	140

For superheated steam in long, straight pipe lines 180 ft. per sec. may be used.

For steam at high pressures, 300 to 500 lbs. per square inch, useful information is given by Broido (*Amer. Soc. Mech. Engineers*, 1922, page 1199), who concludes that for steady flow in pipes over 5 ins. diameter 10,000 to 12,000 feet per min. is advisable, and states that velocities up to 15,000 ft. per min. have been used in larger pipes without undesirable effects.

It should be remembered that the higher the velocity the smaller is the pipe diameter, and hence the external radiating surface is less.

Pressure Drop in Pipe Lines.

The formula (known as the Babcock formula) usually employed to relate the flow, pressure drop, and pipe diameter is

$$W = 87{\cdot}5\sqrt{\frac{D\,(p_1 - p_2)\,d^5}{L\left(1 + \frac{3{\cdot}6}{d}\right)}},$$

where W = weight in pounds; d = diameter in inches; D = density or weight per cubic foot; p_1 = initial pressure; p_2 = pressure at end of pipe; L = length in feet.

This formula corresponds to $p_1 - p_2 = 0{\cdot}0001306\,\frac{W^2 L\left(1 + \frac{3{\cdot}6}{d}\right)}{D d^5}$ and also to $h = f\,\frac{v^2}{2g}\cdot\frac{4L}{d_1}$, where h = loss of head in feet, d_1 = diameter in feet, f = coefficient of friction of the steam in the pipe, f being equal to $0{\cdot}0027\left(1 + \frac{3}{10 d_1}\right)$; this coefficient is due to R. C. Carpenter, and is accepted by Unwin.

The following table gives, approximately, the weight of steam per minute which will flow from various initial pressures, with one pound loss of pressure, through straight, smooth pipes, each having a length of 240 times its own diameter. The table is calculated from the above formula.

TABLE OF FLOW OF STEAM THROUGH PIPES.

Initial Pressure by Gauge.	Internal Diameter of Pipe in Inches. Length = 240 diameters.													
	¾	1	1¼	2	2½	3	4	5	6	8	10	12	15	18

(*Morley.*)

The foregoing table is based on saturated steam. For any other loss of pressure multiply by the square root of the given loss. For any other length of pipe *divide* 240 *by the given length expressed in diameters, and multiply the figures in the table by the square root of this quotient*, which will give the flow for 1 lb. loss of pressure. Conversely, dividing the given length in diameters by 240 will give the loss of pressure for the flow given in the table.

For superheated steam multiply the values in the table by $\sqrt{\frac{\text{density of superheated steam}}{\text{density of saturated steam}}}$ —or *approximately* $\frac{1}{\sqrt{1 + {\cdot}0015\,t_s}}$, where t_s = degrees of superheat.

The loss of head due to getting up the velocity, to the friction of the steam entering the pipe, and passing elbows and valves, will reduce the flow given in the table. The resistance at the opening, and that at a globe valve, are each about the same as that for a length of pipe

equal to 114 diameters divided by a number represented by $1 + (3{\cdot}6 \div \text{diameter})$. For the sizes of pipes given in the table these corresponding lengths are, approximately :—

$\frac{3}{4}$	1	$1\frac{1}{2}$	2	$2\frac{1}{2}$	3	4	5	6	8	10	12	15	18
20	25	34	41	47	52	60	66	71	79	84	88	92	95

The resistance at an elbow is equal to two-thirds that of a globe valve. These equivalents—for opening, for elbows, and for valves—must be added in each instance to the actual length of pipe. Thus a 4-in. pipe, 120 diameters (40 ft.) long, with a globe valve and three elbows, would be equivalent to $120 + 60 + 60 + (3 \times 40) = 360$ diameters long; and $360 \div 240 = 1\frac{1}{2}$. It would therefore have $1\frac{1}{2}$ lbs. loss of pressure at the flow given in the table, or deliver $(1 \div \sqrt{1\frac{1}{2}}$ ·816), 81·6 per cent. of the steam with the same (1 lb.) loss of pressure.

In place of the calculations on the table given in the preceding paragraphs, the following nomographic chart (based on the formula, p. 1745) may be used, and provides a very convenient and sufficiently accurate method of determining pipe sizes, pressure drops, etc.

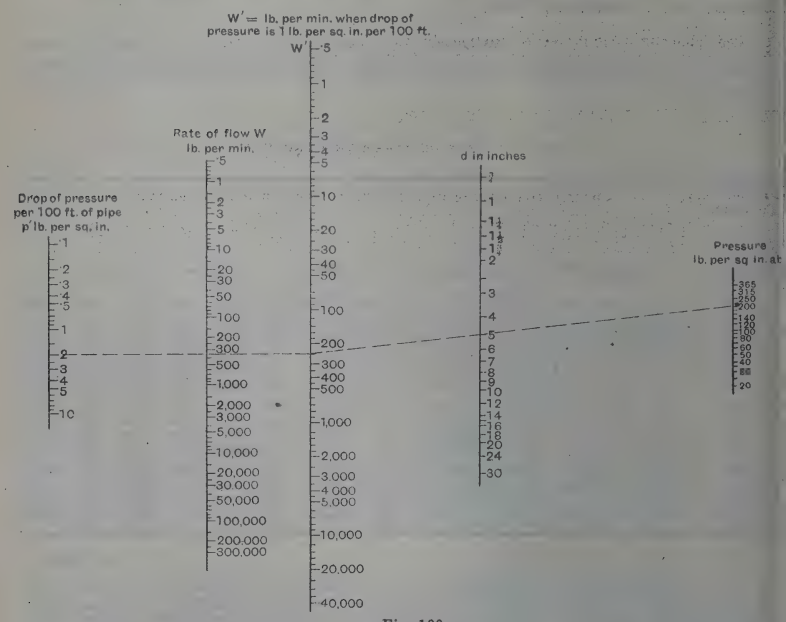

Fig. 100

Method of use of chart :

(*a*) To find diameter for given quantity and pressure drop, join W and p' and produce to cut scale of W′, join point so found to pressure scale at right, read required diameter at intersection with scale of d.

(*b*) To find quantity for given pipe and pressure drop, reverse above process, finding first W′ and then W.

(*c*) To find pressure drop for given pipe and flow, join points on scales of pressure and d, produce to find W′, join W′ to W and produce to cut scale of p' at required value.

Flow of Air and Steam in Pipes.

The Babcock and other formulæ for the flow of steam have recently been reviewed and compared with the results obtained by improved experimental methods.

The conclusions of the investigation made by McAdams and Sherwood (Amer. Soc. Mech. Eng., October 1926) are that for air the best formula is:

$$P_1 - P_2 = \frac{0{\cdot}13 f L Q^2 P^2}{P_a D^5 T}$$

$$\text{or } Q_1 = 2{\cdot}77 \sqrt{\frac{D^5 (P_1 - P_2)\, T}{f L P_1^2}}$$

and for steam:

$$P_1 - P_2 = 0{\cdot}0184 \frac{f L G^2}{D^5 w_a}$$

$$\text{or } G = 4{\cdot}51 \sqrt{\frac{D^5 w_a (P_1 - P_2)}{f L}}$$

where

P_1, P_2 are initial and final pressures in lbs. per sq. in.;
P_a = average pressure, lbs. per sq. in. abs.;
Q_1, Q = cub. ft. air per minute at P_1, P, respectively;
D = inside diameter of pipe in inches;
L = equivalent frictional length of pipe in feet;
= length of straight pipe + 2·5 D × number of elbows;
T = air temperature, ° Fah., abs.;
G = lbs. steam per minute;
w_a = lbs. per cub. ft. of fluid at average temperature and pressure;
f = friction coefficient.

f is given by charts from which the values in the following table are extracted:

Values of $\frac{G}{D}$ for Steam, or $\frac{QP}{DT}$ for Air.	Steam.	Air.

Loss of Heat from Uncovered Steam Pipes.

The large amount of heat lost from bare steam pipes, and the consequent waste of coal, is frequently not fully appreciated. One square foot of uncovered pipe surface, the pipe containing steam at 100 lbs. per sq. in., will dissipate about 3 B.Th.U. per hour per degree of temperature difference between the steam and the atmosphere, or about 850 B.Th.U. per hour at ordinary

atmospheric temperatures. The steam condensed per hour due to this square foot of bare pipe will be 0·96 lb. In a year of 3,000 working hours the steam wasted will amount to 2,880 lbs., corresponding to a coal consumption of about 410 lbs.

A single 9-ft. length of 6-in. pipe, if uncovered, will waste by heat loss about 2·5 tons of coal per year.

80 to 90 per cent. of this loss may be avoided by the use of suitable coverings, the expense of which is amply counterbalanced by the saving in coal.

It is important that flanges, valves, etc., as well as the body of the pipe lengths, should be covered.

The loss of heat per hour per sq. ft. of surface, in the case of bare pipes, depends principally upon the difference of temperature between the pipe—*i.e.* practically, that of the steam in the pipe—and the surrounding atmosphere, but also is influenced to some extent by the diameter of the pipe, its position—whether horizontal or vertical—the presence of air currents about the pipe, the nature of the pipe surface, and the velocity of the steam in the pipe.

Complete data on all these factors are lacking.

It is usually assumed that the loss is proportional to the difference of temperature, but careful experiments show that the rate of loss, B.Th.U. per sq. ft. per degree F., increases at the higher temperature differences. Thus from 1·95 at 50° difference, it becomes 2·4 at 150°, 3·26 at 300°, 4 at 400°, and 5·26 at 460°. (*McMillan.*)

There is little experimental data on the effect of pipe diameter, but it appears that the loss per sq. ft. decreases as the diameter increases, and this is in accordance with theory.

The following table shows the heat loss from pipes covered with various thicknesses of 85 per cent. magnesia composition, and the approximate loss from uncovered pipes is given for comparison.

LOSS OF HEAT FROM STEAM PIPES, WITH STEAM 300° F. ABOVE ATMOSPHERIC TEMPERATURE. LOSS IN B.TH.U. PER HOUR PER SQUARE FOOT OF PIPE SURFACE.

	Pipe Diameter.					
	1 in.	2 ins.	4 ins.	6 ins.	8 ins.	12 ins.

,, 5·0 ,, ,,	—	—	66	58	52	46

(*Based on tests by McMillan, 'Trans. Am. Soc. M.E.'* 1915.)

The 'efficiency' of the covering in preventing loss of heat is taken as the ratio (heat loss from bare pipe — loss from covered pipe) ÷ heat loss from bare pipe. The table shows that this 'efficiency' varies with the thickness and the pipe diameter, hence to compare different covering materials, the comparison must be made under the same conditions of thickness, etc., if the comparison is to show the relative insulating properties.

The coverings may also be compared on the basis of cost per foot run—*i.e.* taking a greater thickness in the case of the cheaper materials.

The relative properties of various pipe coverings are shown in the following table, the thickness being about 1·4 ins., diameter of test pipe 1 in., steam pressures in pipe 50, 100, and 200 lbs. per sq. in.

Relative Value of Pipe Coverings.

Material.	Weigh per foot run, lbs.	Insulating Efficiency per cent.

(*Bradley.*)

Boxes for Pipe Flanges.

In estimating the loss of heat from covered pipe lines, the effect of the boxes covering the flanges in adding to the total area of radiating surface must be allowed for.

For typical flange boxes, assuming one box at each 10 feet of pipe line, the additional area may be taken as about 7 per cent. *i.e.* to find the heat radiated, calculate the pipe surface in square feet, as if there were no flanges, add 7 per cent., and multiply by the appropriate figure from the table on page 1745.

Notes on Coverings for Pipes and Boilers.

As well as having good heat insulating properties, it is important that pipe coverings be durable. A material which easily disintegrates under vibration will not long remain an efficient insulator, nor will a material which cannot stand high temperature. For example, hair felt is a good insulator, but will not stand contact with pipes carrying high pressure or superheated steam.

Tests with locomotive-type boilers, first uncovered and then covered with 2 ins. of 85 per cent. magnesia, showed in the second case 2·5 per cent. additional evaporation for 13·8 per cent. less coal, or a total coal saving of 16 per cent.

(*'Chem. and Met. Eng.,' Feb.* 16, 1921.)

Recent tests at the National Physical Laboratory have shown that 85 per cent. magnesia (that is, 85 per cent. hydrated magnesium carbonate and 15 per cent. asbestos) begins to calcine at 450° F., and that at 600° F. the decomposition is considerable. At the high steam temperatures now coming into use in large power stations (pressures up to 375 lbs. per sq. in. and temperatures up to 700° F.) it is necessary to place next the pipe a material unaffected by heat. About ½ in. of slag wool or of special composition may be used, then a layer of 85 per cent. magnesia or other good non-conductor, and then an outer layer, ½ in. thick, of hard-setting composition to bind the whole together.

Notes on Lagging.

The surface temperature of a lagging, when in use, is commonly supposed by engineers to furnish a clue to its efficiency, and conclusions are often formed from the sensation of heat experienced when the hand is placed on the surface. Another test, frequently employed, is to make

a small hole in the lagging into which the bulb of a thermometer is inserted ; and it is then assumed that the material in which the lowest reading is obtained possesses a superiority in respect to insulating power. Whilst a correct measurement of the temperature of the surface is of value in conjunction with other tests, if taken alone an entirely erroneous opinion of the merit of the material may be formed.

The important factor which is not taken into account in the above rough-and-ready test is the nature of the surface in respect to its radiating power. A lagging with a rough exterior radiates heat with much greater freedom than one which is finished smooth, and the latter which is superior as an insulator, owing to retention of heat by the surface, will feel hotter than the former when touched by the hand. Hence it follows that a given non-conducting coating, if improved by painting and varnishing the surface, would appear to have suffered in insulating power if judged by its surface temperature only. To avoid such a fallacious conclusion, it is evident that the radiating power must also be taken into account, and only when this is done can a correct inference be drawn.

When the radiating surfaces are identical, the surface temperature furnishes a reliable and delicate guide to the insulating powers of different materials. A smooth metallic surface, such as aluminium paint, may be hotter than an unprepared surface, and yet radiate less.

On reference to a test in which a thermometer bulb is placed in a hole made for the purpose in the outer part of the lagging, into which it is customary to pour mercury to secure a good contact between the material and the bulb of the thermometer, it is difficult to say what the reading indicates, as the temperature recorded will be the mean of that existing between the end of the bulb and the surface ; and, moreover, the normal condition of the lagging at this part is entirely changed by the introduction of the mercury and thermometer bulb. One thing is certain : that the reading affords no clue to the surface temperature it is supposed to measure ; and in this respect the test is inferior to the application of the hand. The thermal-junction method is undoubtedly the best for obtaining a definite reading of the surface temperature : and as it is now possible to obtain cheap portable indicators for use with a junction, other so-called measurements should be definitely abandoned.

The relations between surface temperature and efficiency may be summarised as follows :—

1. When the surface of a given insulating material is treated so as to reduce its radiating power, the temperature is higher, although the heat escaping is less.

2. If two different materials possess identical surfaces, that which has the higher surface temperature, under given conditions, is the worse insulator.

A recognition of these two points will prevent engineers from being led astray by the extravagant claims frequently put forward for compositions, based entirely on imperfect surface temperature measurements. The advantage of finishing the surface with aluminium paint instead of ordinary paint and varnish, should be recognised, as not only is the insulating power improved, but the finished work has a better appearance. The fact that such a surface feels warmer to the touch is in this instance not a proof of inferiority, but of the contrary.

(*C. R. Darling*, '*Engineering*,' *Sept.* 22, 1911.)

The holding of slag wool to pipes or boilers (to which asbestos composition has been applied) is best effected by means of wire-bound split laths, so spaced that the finishing overlay of cement may not only be keyed in between them but may also afford a means of locating any leakages, in addition to preserving a favourable density estimated at from 10 to 12 lbs. per cubic. foot.

A cheaper but decidedly less effective way of holding slag wool together is by means of wire netting in the meshes of which an overlay of plastic cement is impacted. When, therefore, disintegration takes place and the wool settles down by its own gravity, the upper surface is reduced to a mere shell of wire and cement by which the bulk is held in suspension.

Silk waste, although almost equal in efficiency to slag wool, is wanting in durability.

Hair-felt is one of the finest non-conductors known, but is quickly consumed by direct contact with heated surfaces. See also pp. 1751, 1752. (*E. Kenyon.*)

STEAM DRYERS AND WATER SEPARATORS.

STEAM TRAPS

Dry steam plays a far more important part in the efficiency of engines and boilers than is generally recognised, the economical efficiency of an otherwise high-class plant being frequently marred by the waste, condensation, broken joints, etc., due to wet steam.

Water carried forward from the boiler by priming, although it does no work whatever, is nevertheless heated up to the same temperature as the steam itself, and therefore represents a loss in coal proportionate to its weight. All boilers prime more or less, but priming is invariably heavy in boilers that are worked to their limit, or in any way hard pushed.

An engine may give a satisfactory diagram and yet be anything but economical if regard is had to the quantity of water contained in the steam, or to the amount of condensation in the cylinder, which the presence of water greatly increases. In the same way a boiler may appear to have a high evaporative efficiency, judged by the quantity of water it disposes of, whereas its efficiency would frequently appear in quite a different light if judged only by the amount of water it evaporated, *i.e.*, gave off as dry steam.

Dry steam itself is not a good conductor of heat, but water is, and therefore its presence in steam pipes and cylinders should never be permitted, as by acting as a conductor between the steam and the metal it sets up active condensation and absolutely prevents economical results being obtained, even in engines of the best design.

Wet steam is very deleterious in steam turbines, causing erosion and abrasion of the blading and deposition of solid matter on the blades and passages.

In addition to the above considerations, there is also the fact that water in steam pipes invariably causes leaky joints and other annoyances of a nature only too well known.

A separator should be fitted near the engine, unless the steam is superheated, in which case the separator is of questionable service, any water drained from it being probably due to the large surface of the separator itself offers for cooling by radiation.

Separators as a rule act by causing change of direction of the steam, either giving it a definite whirling path, or by causing it to pass down one side and up the other side of a vessel having in it a plain vertical baffle.

STEAM TRAPS.

Steam traps are indispensable adjuncts to steam apparatus in which water of condensation must be drained off with regularity and certainty, and without loss of steam.

A steam trap should work reliably and economically and without adjustment with considerable fluctuations of steam pressure, and working parts should be readily accessible without having to disconnect pipes.

All steam traps are either of the expansion (thermostatic) or float (bucket) type. The three main groups of expansion traps work (*a*) on expansion and contraction of metal tubes, (*b*) on expansion and contraction of either a liquid enclosed in a tube actuating a valve attached to a piston (cartridge type), or expansion and contraction of a rod other than metal, to which the valve is attached, and (*c*) on expansion and contraction of volatile liquid enclosed in a capsule or bellows (vapour type).

Float traps are made either with closed (ball) float or with open floats operating valves either directly, or through levers, or operating pilot valve only, the main valve being operated by the steam pressure.

Expansion traps on account of their small dimensions are generally preferred for draining individual steam-heated appliances (radiators, calorifiers, evaporators, etc.). When cold they are always wide open and therefore do not require venting devices.

Float traps are desirable for draining collecting drain pipes, steam mains, oil separators, and generally where sudden variations in water quantity are likely.

'THE BRADFORD' STEAM TRAP.

(*United States Metallic Packing Co., Ltd., Soho Works, Allerton Road, Bradford.*)

'The Bradford' Steam Trap embodies a new principle in this class of device. It is a float trap, but with an important difference. The float does not open or close the discharge valve. It simply releases or engages a weighted lever, which is so arranged that the outlet is instantaneously opened or instantaneously closed. There is no middle position. This effectually prevents the wire-drawing of the discharge, which cuts the valve and seat and so destroys the efficiency of those traps where the opening and closing take place gradually.

The method of operation is as follows (fig. 101). The water accumulates in the collecting chamber and gradually raises the float until the latter reaches the desired point, when it trips the weighted lever, which immediately opens the discharge to its fullest extent. The water is

then forced out under full pressure until it reaches the bottom level, when the lever is again tripped and the discharge is at once closed. The outlet is always submerged, so that there can be no escape of steam.

The apparatus is made in two classes, viz. the piston-operated trap and the direct-operated trap. Fig. 101 represents the piston-operated trap, in which the discharge valve is operated by the steam acting on a piston working in a cylinder. By this method the maximum diameter of outlet opening is obtained without reference to the steam pressure. This is a most important feature, as in consequence of the unusually large outlet the trap will deal equally well with flooding and priming as with ordinary condensation. In the direct-operated trap the action is simpler, the discharge being opened and closed directly from the trip lever, but the area of the outlet is smaller.

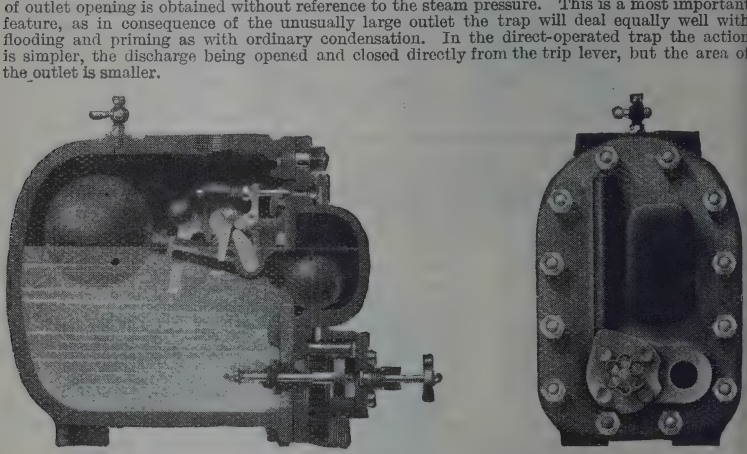

FIG. 101.—Piston-Operated Trap.

The traps will work at any pressure from 250 lbs. downwards, and are made in several sizes. The piston-operated traps will discharge from 10,000 to 160,000 gallons per hour when working at 100 lbs. pressure. In the direct-operated traps the discharge capacities range from 325 to 1,800 gallons per hour at 100 lbs. pressure. Both traps will force the discharge water 1 foot high for every pound of steam pressure.

An *eliminator*, which combines the above trap with a convenient form of separator, is also prepared, the manufacturers being The United States Metallic Packing Co., Ltd., of Soho Works, Allerton Road, Bradford.

THE 'DRAYTON' DIFFERENTIAL STEAM TRAP.

(The Drayton Regulator and Instrument Co., Ltd., West Drayton.)

This arrangement, fig. 102, consists of two sections: (1) the 'Drayton Capacity Multiplier,' (2) the 'Euston' all-metal thermostatic steam trap.

The 'Drayton Capacity Multiplier' is a pear-shaped vessel having a central tube to the outlet and a nozzle situated at the highest point thereof. The entrance to the nozzle is controlled by a throttling screw with outside adjustment.

The 'Euston' steam trap contains an inner tube which forms an expanding element and carries a valve seat at its higher end. The valve is supported by a spindle passing through the trap cover and held by a thread in an exterior bridge.

Condensate and steam pass freely into the body of the Capacity Multiplier. The condensate rises evenly inside and outside the central tube by virtue of the steam pressure being transmitted to the central tube through the nozzle. The steam, having free access to the trap, expands the inner tube and the valve is held closed.

When the condensate rises sufficiently high in the capacity multiplier to seal the lower end of the nozzle, the steam is shut off from the trap; condensation causes a rapid fall of pressure in the trap and the central tube of the capacity multiplier, which permits the pressure in the main body of the capacity multiplier to lift the condensate into the trap.

The condensate which has been longest in the capacity multiplier is the first to enter the trap, and the considerable difference in temperature between this and the steam causes immediate

contraction of the inner tube of the trap and opening of the trap valve ; the condensate, therefore, is expelled through the valve, and passes to the outlet down the annular space between the inner and the outer tubes, thereby expediting the opening of the valve to its fullest extent.

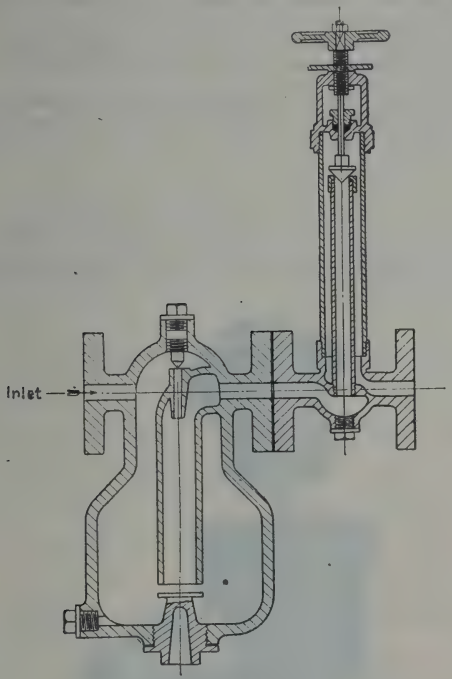

FIG. 102.

The nature of the discharge depends entirely on the amount of condensate handled. When the rate at which condensate accumulates in the capacity multiplier is slower than the rate at which it can be discharged through the trap valve, the action is intermittent ; under these conditions it will be found that the trap opens and closes sharply ; there is little or no live steam lost after the

Size	A	B	C	D	E	F
ins.	ins.	ins.	ins.	ins.	ins.	ins.
$\frac{1}{2}$	$2\frac{5}{8}$	$8\frac{3}{4}$	$5\frac{3}{4}$	$3\frac{3}{4}$	$3\frac{3}{8}$	$10\frac{3}{8}$
$\frac{3}{4}$	$2\frac{5}{8}$	$8\frac{3}{4}$	$5\frac{3}{4}$	4	4	$10\frac{1}{2}$
1	$2\frac{5}{8}$	$8\frac{3}{4}$	$5\frac{3}{4}$	$4\frac{3}{4}$	$4\frac{1}{2}$	11
$1\frac{1}{4}$	3	13	8	$5\frac{1}{2}$	$5\frac{1}{2}$	$12\frac{3}{4}$
$1\frac{1}{2}$	$3\frac{1}{4}$	13	9	$5\frac{1}{2}$	6	14
2	4	18	10	$6\frac{1}{2}$	$7\frac{1}{8}$	$15\frac{1}{8}$

trap has finished discharging. On the other hand, if the rate at which the condensate accumulates in the capacity multiplier approaches or equals the rate at which the trap valve permits discharge, the action is continuous.

When the level of the condensate in the capacity multiplier sinks to the lower end of the central tube, steam passes into the trap, closes the valve, by expanding the inner tube, and the cycle commences again. As condensate is continuously trickling into the trap, the level in the

capacity multiplier will commence to rise as soon as the flow up the central tube is broken by the unsealing of the lower end of the nozzle.

All grit, dirt, and other impurities which may come through with the steam and condensate, are retained in the base of the capacity multiplier by the mud stool. A plug is provided for draining out periodically.

To adjust for any working pressure, the valve should be advanced towards or withdrawn from the valve seat. This can easily be done by means of the hand wheel provided.

Condensate can be lifted 2 ft. for every pound of steam over 5 lb. per sq. in., if a check valve is fitted on the outlet.

The 'Drayton Differential' is made in materials suitable for any pressure of saturated or superheated steam. When used for pressures under 40 lbs. per sq. in. the 'Euston' is made with longer internal and external tubes.

Sizes up to 1¼ in. are fitted with cone metal-to-metal valves; 1½ in. and 2 in. traps are fitted with flat metal-to-metal valves.

'Drayton' Balanced Pressure Trap.

(The Drayton Regulator and Instrument Co., Ltd., West Drayton.)

Fig. 103 shows the 'Drayton' Balanced Pressure Trap with cover and thermostatic element removed. This trap is of the thermostatic type and utilises the difference in temperature between steam and water.

Fig. 103.

The particular feature of the 'Drayton' Balanced Pressure Trap is that the thermostatic element is so filled that the difference in pressure inside and outside the bellow chamber remains constant, no matter what the actual pressure outside the thermostatic element may be.

In place of the usual diaphragm, a bellows of large diameter is employed, and the length of the bellows is such that the valve has a lift of $\frac{3}{16}$ in.

This trap requires no adjustment for varying steam pressures, and opens and closes sharply

General Notes on Steam Trap Practice.

Steam traps when cold should be wide open, or air vents should be provided so that at starting all air and water are expelled from the pipes when steam commences to pass. The traps close automatically, so that there is no possible chance of water hammer and rents occurring in pipes through an accumulation of cold water suddenly receiving the impact of live steam, the cause of many accidents.

The traps should always be fixed at a point where a droop or bend in the pipe is situated, and at the lowest possible point.

In the event of the drain pipe being screwed into a cylinder or pipe, great care should be taken that the drain does not rise above the inside of the vessel or pipe, otherwise perfect drainage is not possible.

It will be found that if a length of pipe is fitted between traps and vessels to be drained, so as to form a reservoir for the water, it will greatly facilitate the easy working of the trap, as the discharge water is much cooler, and enables the trap to do a larger amount of work than it would do under ordinary conditions.

Every lb. per sq. in. pressure balances a column of water 2¼ ft. high, so that in arranging for tanks, if 2 ft. of water for every 1 lb. of steam pressure is allowed for, the allowable height for placing the tank can be ascertained. In this case a non-return valve, similar to a boiler feed check valve, should be placed on the outlet side when the trap is used for lifting water, to prevent the water returning into the pipes when main steam is shut off.

When discharging into a sealed drain it is advisable to fit a three-way cock to the outlet, so that the trap can be adjusted with the cock opened to the atmosphere. There is an additional advantage in having a three-way cock fitted, as the working of the trap can be inspected at all times by simply opening the cock to the atmosphere.

By blowing the pipes through with live steam before fixing the trap, the dirt will be cleaned out, and much trouble saved in the after working of same.

The greatest precaution taken cannot always prevent grit getting into the pipes, and if same is not blown out at starting it is likely to get into the trap and become fixed in the seat or valve face. The consequence is, the trap is likely to let steam pass. Steam at high pressure cuts almost as badly as compressed air, and the longer the steam is allowed to blow through, the worse the valve is cut; when this takes place the valve should be examined, and, if cut, it should be trued up in a lathe, or if badly cut it should be renewed.

Steam issuing from the discharge of a high-pressure trap is not a proof of steam leakage, Wherever water under pressure and at a temperature above 212° is released to the atmosphere, about 1 per cent. will flash into steam for each 10° by which the original water temperature exceeds 212°.

Selection, Installation, and Upkeep of Steam Traps.*

(Abstract.)

The two main factors to be considered in selecting traps are (1) the steam pressure at the trap, and (2) the amount of condensation to be handled. It should be carefully noted that the steam pressure desired is that at the trap, not the boiler pressure or the pressure at some

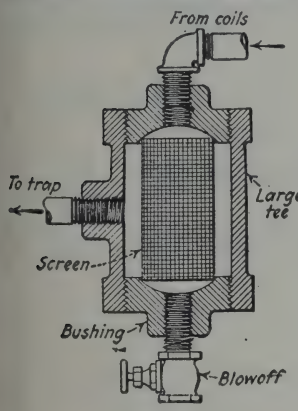

FIG. 104.

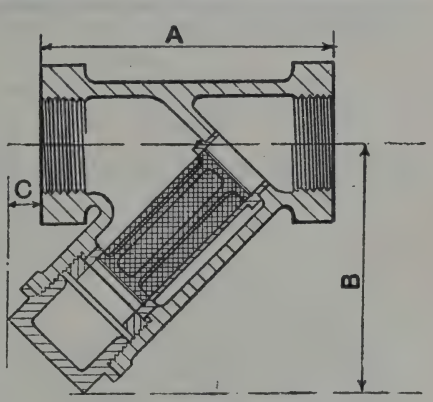

FIG. 105.

point near the trap. Where the pressure varies, the trap should have the correct opening for the higher pressure, yet it should have ample capacity to operate on the lower pressure.

The best practice is to put a separate trap on each steam coil, drying cylinder, steam main, steam separator, etc.,

When a trap is attached to a piece of apparatus using superheated steam, care must be taken that the steam is not superheated when it reaches the trap, otherwise the latter will not operate.

* E. Smiley, *Power*, July 11, 1922.

Drips on superheated lines are necessary to handle such conditions as the priming of the boilers In such cases the connection to the trap must have enough radiating surface to ensure condensa tion for the trap to work on. Traps of the continuous-discharge type and many of the bucke traps require a certain amount of water in the body. If superheated steam gets into the trap it re-evaporates the water and causes leakage and wiredrawing. On account of the tendency to wiredrawing with superheated steam and with apparatus operating at high pressure with but little condensation, a special metal should be provided in the valve and seat.

The best way to avoid trouble from dirt, scale, or sediment is to use a 'strainer' like that shown in fig. 104, which is easily made up from pipe fittings and a strip of heavy brass or copper wire screen made in the form of a cylinder, so that it will fit in the recesses of the bushing. Another convenient type of strainer is that shown by fig. 105, and made by *The Drayton Regulator and Instrument Company, Ltd., West Drayton*, which can be inserted into pipe line at the trap inlet side and can be cleaned without breaking the pipe line.

A strainer requires occasional cleaning, but that is a simple matter compared to cleaning the trap.

Many traps are provided with blow-off pet-cocks or valves, so that the traps can be blown down and cleaned out periodically. A simpler but less efficient remedy is a dirt leg in the piping in front of the trap. This can be made up with a tee, long nipple and cap. Excessive oil in the line can usually be traced to a faulty oil separator in the system.

The only way to be absolutely sure that a trap is clean is by an examination of the interior. In fact, it is good practice to inspect traps at least once or twice a year.

Although 1 lb. pressure at the trap will support 2·4 ft. of water at 212 deg., it is well to figure back pressure at the rate of about one pound for every two feet of head. This makes a reasonable allowance for friction in the pipe and fittings.

High-pressure traps should not in general discharge into sealed return pipes under a low pressure, as the breaking into steam (or flashing, as it is called) of the high-temperature water upon release will cause snapping and water hammer in the pipes. It is usually best for all traps, when the condensation is to be saved, to discharge into a vented receiver above the water line. This prevents any backing up or water hammer, and also gives an opportunity to detect severe steam leakage by an inspection of the outlet to the vent pipe leading from the trap.

A general rule on the location of a trap is to keep it below the lowest water level in the unit it is draining. This keeps the discharge line free of condensation when the pipes get cold on intermittent service, and thereby decreases the possibility of water hammer.

Traps that are outside and likely to be injured by freezing should be insulated and located as near the heating unit as possible. Their discharge lines should also be automatically drained in case they rise above the lowest water level of the trap. This prevents the condensation from flowing back into the traps when the pressure is taken off. It is of primary importance that they be accessible for periodic inspection.

Expansion of Steam.

It is found in practice that in engines using saturated steam the expansion line follows closely the hyperbolic law :—

absolute pressure × volume = a constant.

Hence it is usual to compute indicator diagrams on the assumption that the expansion is hyperbolic. With highly superheated steam the pressure falls more rapidly than the hyperbolic curve indicates.

Referring to fig. 1, the theoretical indicator diagram is A B C D O, there being no clearance and a perfect vacuum. Steam is cut off at B and exhausted at C.

FIG. 1.

p = absolute pressure in lbs. per sq. in.;

u = volume in cubic feet;

R = ratio of expansion = $\frac{OD}{AB}$;

W = area of diagram;

P = mean effective pressure in lbs. per sq. in. (M.E.P.);

pu = a constant.

then $W = ABCE + ECDO$

$= p_2u_2 \text{ hyp. log } R + p_2u_2$.

$$P = p_1\left(\frac{\text{hyp. log } R + 1}{R}\right) = p\ K.$$

TABLE OF MEAN PRESSURE CONSTANTS K.

The table also gives the points of cut-off (nominal), based on assumed cylinder ratios, L.P. to H.P., in the case of multiple-expansion engines.

(*Morley.*)

The referred M.E.P. of compound engines is the equivalent M.E.P. if the entire expansion were to take place in the low-pressure cylinder.

The nominal ratio of expansion is the stroke volume of the L.P. cylinder ÷ volume swept by H.P. piston up to point of cut-off, or

$$R = \frac{V_L}{a\ V_H} = \frac{\text{cylinder ratio}}{a}$$

where V_H, V_L are stroke volumes of H.P. and L.P. cylinders, and a is proportion of stroke at which cut-off takes place in the H.P. cylinder.

If C_H and C_L are the clearance volumes at each end of the H.P. and L.P. cylinders, the real ratio of expansion is

$$\frac{V_L + C_L}{a\ (V_H + C_H)}$$

To determine the probable actual mean pressure (referred to the low-pressure cylinder in the case of a multiple-expansion engine) multiply the initial pressure (absolute) by K, deduct the back pressure, and multiply by a suitable 'diagram factor.'

THE PAXMAN Positive Valve Gear engines are suitable for boiler pressures up to 200 lb. per square inch, with a total steam temperature up to 600 degrees Fahr.

The economy of the steam consumption of these engines is remarkable, it being possible to obtain one-horse power for every $9\frac{1}{2}$ to $10\frac{1}{2}$ lb. of superheated steam.

With an installation comprising our 'Economic' type of boiler and Positive Valve Gear engine combined, we are able to guarantee consumptions of 1·1 to 1·2 lb. of coal per I.H.P. per hour under suitable conditions.

The PAXMAN Positive Valve Gear lends itself to the easy conversion of existing engines to Paxman-Lentz type. Under actual practice, improvements and economies in steam consumption up to 26% have been obtained with a great reduction in maintenance costs.

Steam Engines and Boilers of all types. Superheaters, Gas Engines and Producers.

DAVEY, PAXMAN & CO. Ltd.,
Colchester, and Aldwych House, Aldwych, W.C.2.

G.H.W.

F. 1761

Diagram factors depend on the type of engine, type of valves and valve gear, jacketing, superheating, speed, etc. Approximate typical values are as follows:—

TABLE OF DIAGRAM FACTORS.

Triple-expansion	·65–·75
Compound condensing, superheated	·65–·75
„ „ saturated	·7– ·8
„ non-condensing	·8–·85
Simple condensing, trip gears	·9–·95
„ „ slide valves	·85– ·9
„ non-condensing	·9–·95

Note.—In calculating the M.E.P. the clearance is ignored. If the clearance is allowed for, the ratio of expansion for a given cut-off is lower and the theoretical M.E.P. higher, necessitating a lower diagram factor, particularly for simple and compound engines. Thus, some authorities give from 0·7 to 0·9 for simple engines.

Low revolutions, large clearance, jackets, reheaters, and low compression increase the diagram factor. These special conditions must be allowed for, as in slow-speed pumping engines.

Usual Expansions in Various Types of Engines.

Single Condensing Engines	from 2 to 5 times
Two-cylinder Compound Engines	„ 10 „ 20 „
Triple-expansion Engines	„ 12 „ 25 „
Quadruple-expansion Engines	„ 16 „ 30 „
Uniflow Engines	„ 7 „ 12 „

INDICATED HORSE-POWER OF STEAM ENGINES.

P = Mean effective pressure, in pounds per square inch;
A = Area of cylinder in square inches;
L = Stroke in feet;
N = Revolutions per minute;

then

$$\text{I.H.P. (for a double-acting engine)} = \frac{2\ PLAN}{33{,}000}$$

(See also p. 1773.)

The I.H.P. of a compound or multiple expansion engine is the sum of the powers of the individual cylinders, each calculated as above. For such engines, the 'referred M.E.P.' or 'M.E.P. referred to the L.P. cylinder' is frequently spoken of and used in designing. It means that M.E.P. which, if it acted in a single cylinder of the same dimensions as the L.P. cylinder of the compound engine and working at the same speed, would produce the same power.

The '*referred M.E.P.*' is thus equal to M.E.P. of H.P. cylinder $\times \frac{\text{H.P. cylinder area}}{\text{L.P. cylinder area}}$

$+$ M.E.P. of I.P. cylinder $\times \frac{\text{I.P. cylinder area}}{\text{L.P. cylinder area}} +$ M.E.P. of L.P.

For a two-cylinder compound engine the middle term disappears.

Brake Horse-Power (B.H.P.).

'Brake' or 'Effective' or 'Actual' horse-power is the horse-power delivered by the engine to whatever it is driving. If the engine shaft is coupled to the driven machine—such as a generator for electric power, or a rolling mill, or whatever it may be—the B.H.P. is the power transmitted at the coupling. For a rope drive it is the power at the engine rope pulley. In all cases the B.H.P. is the indicated H.P. less the power absorbed in the running of the engine itself. This latter power—the frictional H.P.—is about 10 per cent. in good modern engines, 8 per cent. in those of the highest class, but may be as much as 20 per cent. in small engines of crude design.

Mechanical Efficiency.

The 'mechanical efficiency' is the ratio of B.H.P. to I.H.P. For high-class engines of, say, 100 H.P. and upwards, typical values of the mechanical efficiency at various loads are as follows:—

Load	Full	¾	½	¼
Mechanical efficiency, per cent.	92	90·5	88	80·5

STEAM CONSUMPTION.

The ideal steam-engine cycle, adopted as a standard of comparison, is the Rankine cycle. In it the steam is fully expanded adiabatically, and there are no losses due to throttling, clearance, leakage, condensation, etc.

The following tables show the work done (in B.Th.U.) per lb. of steam, and the steam consumption per i.h.p. hour in the case of ideal engines:—

(1) when the expansion is incomplete;
(2) when the expansion is complete—*i.e.* the Rankine cycle.

TABLE OF STEAM CONSUMPTION AND WORK DONE BY STEAM.

(1)

Theoretical lbs. of steam per i.h.p. hour and work done in B.Th.U. per lb. of steam, assuming adiabatic expansion from dry steam and no compression or clearance losses, to:—

(1) 25 lbs. release pressure with 16 lbs. back pressure.
(2) 10 lbs. release pressure with 2 lbs. back pressure.

All pressures are in lbs. per square inch absolute except the approximate gauge boiler pressure corresponding to the absolute initial pressure at the engine. A pressure drop of 5 lbs. between boiler and engine is assumed.

The correction given in the table is the change in theoretical steam consumption for one pound change in the back pressure, other conditions remaining unaltered.

Boiler Pressure lbs. gauge.	Initial Pressure absolute.	Back Pressure, 16 lbs. absolute.			Back Pressure, 2 lbs. absolute.

50	28·6	12·0	11·2	10·2	89	211	227	249

(*Morley.*)

The steam consumption, lbs. per i.h.p. hour = 2545 ÷ work done, B.Th.U. per lb.

For pressures of 100 to 200 lbs. per sq. in. and back pressures 1 to 2 lbs. per sq. in., the steam consumption of the ideal (Rankine) engine decreases about 6 per cent. for each 100° F. of superheat.

EFFICIENCY OF ENGINES.

The thermal efficiency—of the engine alone, exclusive of boiler plant—is the ratio of the work done per lb. of steam (in B.Th.U.) to the heat required to generate 1 lb. of steam, at the pressure and temperature, at the engine stop valve from feed water at the temperature of the engine exhaust.

$$\text{Thermal efficiency } e = \frac{\text{I.H.P.} \times 42{\cdot}42}{w\,(H_1 - h_2)} = \frac{\text{I.H.P.} \times 2545}{W\,(H_1 - h_2)}$$

where,

w = steam used, lbs. per minute; W = do., lbs. per hour;
H = total heat at pressure and temperature at boiler side of engine stop valve;
h_2 = water heat at temperature of exhaust.

It is customary to express the performance of engines in steam consumption per h.p. hour, but since the heat required to generate the steam increases with pressure and temperature, the steam-consumption figure alone is not a complete criterion of the merit of the engine.

It has been proposed to state the performance of engines in B.Th.U. per minute per i.h.p $= \frac{w\,(H_1 - h_2)}{\text{I.H.P.}} = \frac{42{\cdot}42}{e}$, or in 'equivalent feed,' which is the weight of steam which would be required per i.h.p. hour if $H_1 - h_2$ were 1100, thus equivalent feed $= \frac{W}{\text{I.H.P.}} \times \frac{H_1 - h_2}{1100}$.

Neither of these proposals has been widely adopted.

EFFICIENCY RATIO.

The ratio of the thermal efficiency of the actual engine to that of the Rankine cycle—or of the steam consumption of the Rankine cycle to the actual steam consumption (both having the same pressure, superheat, and vacuum (or back pressure))—is the 'efficiency ratio.'

The efficiency ratio varies with the pressure, superheat, and vacuum, as well as with the merit of the engine as regards freedom from condensation, leakage, and other losses.

Nevertheless the 'efficiency ratio' is useful in comparing engine test results and in predicting steam consumptions.

Economy of High-pressure Working.

The consumption of steam in pounds per horse-power per hour decreases as the pressure rises. The actual steam consumptions vary according to the size and type of engine.

It is estimated that the saving resulting from pressure increase from 200 lbs. to 500 lbs., keeping steam temperature constant at 600° F. and vacuum at 28 ins., would be $1,400 per annum per 1,000 kw. (assuming boiler efficiency 70 per cent., load factor 60 per cent., and cost of 14,000 B.Th.U. coal $5 per ton). Capitalised at 17 per cent., this corresponds to a saving of $8·25 per kw. compared with a probable cost of $3·50 per kw. to work at the higher pressure.

(*J. T. Foster, in 'Electrical World,' May* 11, 1918.)

Steam Saving by Superheating.

Superheating improves the efficiency ratio, so that in practice the saving due to superheating is much greater than that calculated for the Rankine cycle.

Superheating reduces the steam consumption approximately at the rate of 1 per cent. for each 10° F. of superheat, but the rate is rather greater for the lower grades of superheat and less for higher grades.

The practical steam and fuel economy due to the use of superheated steam are about as follows, all superheats being measured at the engine stop valves :—

Approximate Percentage Reduction in Steam Consumption by Superheating, for Compound and Uniflow Engines.

Superheat, deg. Fahr.	50	100	150	200
Common Steam and Exhaust Ports . . .	12	20	26	30
Separate " " " . . .	10	16	21	25
Uniflow, about	8	12	17	21

(*Foster.*)

Superheat reduces the steam consumption most in simple engines.

For superheat in steam turbines see Part IV, page 1833.

The advantages of superheating in general are chiefly :—

1. Greater thermal efficiency of the engine, due to reduced condensation loss.
2. If the boiler plant is not provided with very ample heating surface the addition of a superheater increases the boiler plant efficiency and capacity apart from the engine effect.
3. As compared with saturated steam, higher steam velocities in the pipes may be used with superheated steam, and consequently the pipes may be smaller. For this reason, the percentage loss of heat in the pipe system is lower, in spite of the higher temperature.
4. Reduction in size of auxiliary plant owing to smaller weight of feed water and coal.

Degree of Superheat.

In modern practice the following are usual :—

1. General engine practice : superheat at boilers 150° F., or, say, 120° to 130° at engine. Up to 650° F. total temperature, say 260° F. of superheat at 200 lbs. pressure, can be used if the engine is designed for it.

2. General turbine practice: superheat at turbine 200°–250° F., say up to 650° F. total temperature.

3. Latest turbine practice: superheat at turbine of 250° to 300° F., say up to 750° F. total temperature, at about 350 lbs. sq. in. pressure.

In general, with flat slide or Corliss valves on the high-pressure cylinder, the lower temperatures (about 550° F. total temperature) must not be exceeded.

Characteristics of Superheat.

Condensed steam is a slight lubricant. The absence of this must be met by adequate lubrication when using superheated steam. The high temperature requires a special oil of high flashpoint. Pipe friction losses are reduced by superheating.

In reciprocating engines a later cut-off is required to develop the same horse-power. Hence the maximum power which can be developed is slightly reduced by superheating.

Very high superheats lead to growth and distortion of cast-iron turbine cylinders. Steel should be used at the high-pressure end.

Moderate superheat, about 50° or 100° F., is desirable for evaporating and similar heating purposes, especially with long pipe mains, but very high superheats are undesirable, as the steam should have little, if any, superheat by the time it reaches the heating surfaces of the evaporators.

Throttling slightly raises the superheat in steam; expansion, as in a turbine nozzle, very greatly reduces it.

Except for very moderate superheat, cast-iron and copper must not be used for pipes and valves in contact with the steam.

STEAM JACKETS.

Steam jackets are rarely adopted to-day except for slow-running engines. There is no doubt that a well-arranged jacket leads to considerable economy when the engine is supplied with saturated steam. The economy is much less marked with superheated steam, especially as jackets are usually arranged. Having regard to the extra first cost and complication, jackets are not to be recommended with superheated steam unless the conditions are exceptional.

The usual arrangement of steam supply is defective; the steam is supplied to the jacket and a trap fitted to drain away the condensed steam, but there is no through flow. Usually, on intermediate and low-pressure cylinders the jacket steam pressure is reduced to a few pounds above the steam chest pressure; except to relieve the cylinder barrels and liners of mechanical stress, there is no justification for such an arrangement; from the point of view of steam economy it is ridiculous and largely nullifies the value of the jackets. Wherever possible, the jacket steam should have a through flow. With saturated steam the engine steam should pass through the jackets and then through a water separator before entering the cylinders.

When jackets are used with steam superheated 100° F. or more, they are unnecessary on the high-pressure cylinder.

Small and slow-running engines benefit most from jackets.

Reheaters, *i.e.* appliances for heating the steam in the receivers between the cylinders, do not appear to be useful with saturated steam.

With good initial superheat, say over 150° F., reheaters give good results.

Steam Consumption.

Typical steam consumptions, with the corresponding efficiency ratios, are shown in the following table:—

TYPICAL STEAM CONSUMPTIONS AND EFFICIENCY RATIOS.

Type of Engine.	Pressure at Stop Valve. Lbs. per Sq. In. (Gauge.)	Superheat °F.	Condensing.		Non-Condensing.	
			Steam. Lbs. per I.H.P. Hour.	Efficiency Ratio.	Steam, Lbs. per I.H.P. Hour.	Efficiency Ratio.
Simple	160	—	17 to 17·5	51 to 49	21 to 22	67 to 64
	160	150	12 to 13	65 to 61	16 to 17	78 to 74

	80	150	—	—	20·5 to 21·5	81 to 77
Triple	200	—	11·5 to 12	72 to 69	—	—
	200	150	10 to 10·5	75 to 71	—	—
	180	—	12 to 12·5	70 to 67	—	—
	180	150	10·2 to 11	75 to 70	—	—
Uniflow	200	—	11·8 to 12·3	70 to 67	—	—
	200	150	10 to 10·5	75 to 71	—	—
	160	—	12·5 to 13	69 to 66	19 to 20	74 to 70
	160	150	10·5 to 11	75 to 71	16 to 17	78 to 74
	120	—	13·5 to 14·5	68 to 63	21·5 to 22·5	73 to 69
	120	150	11·5 to 12·5	72 to 67	18 to 19	78 to 73

The particulars in the table refer to high-class modern engines with Corliss or drop valves, and of about 600 i.h.p. or upwards working at normal full load.

In the case of condensing engines, the vacuum has been taken as 26 ins.

The non-condensing uniflow values are subject to considerable variations.

The figures given being for engines of the highest class, for good average practice add from 5 to 10 per cent. For badly clothed or defective engines add 20 per cent. or more. For small engines add from 5 per cent. upwards according to size. The superheat is measured at the engine stop valve. The loss of temperature between superheater and engine may be from 20 to 100 degrees, according to steam-pipe conditions. Simple (alternating-flow single-cylinder) engines vary a good deal according to the cut-off. In general, a uniflow has a rather lower steam consumption than a good compound engine.

Duty of Engines.

The duty of an engine is rarely spoken of except for pumping engines, and is then expressed in terms of the work done in lifting the water per 1,120 lbs. of steam used, or some other basis. Sometimes 1,000 lbs. of steam is used, especially in America; and sometimes coal or heat units is the basis.

Example.—Pumping engine consumes 14 lbs. of steam and 1·8 lbs of coal per water, or pump h.p. hour. The total heat added per lb. of steam is 1,125 B.Th.U.

Duty per 1,120 lbs. steam is $\frac{1,120}{14} \times 33,000 \times 60$ . . . . = 158,400,000 ft. lbs.

Duty per 112 lbs. coal is $\frac{112}{1·8} \times 33,000 \times 60$ . . . . . = 123,200,000 "

Duty per 1,000,000 B.Th.U. in steam is $\frac{1,000,000}{1,125} \times \frac{158,400,000}{1,120} = 125,700,000$ "

The steam consumption of high-class slow-speed triple-expansion pumping engines is very low.

The duty of Winding Engines is rarely measured, but is sometimes stated in terms of steam used per shaft h.p. hour, or per h.p. hour in the coal hoisted. This steam consumption increases greatly when the cages are not fully loaded and the number of winds is below maximum. Under favourable conditions compound non-condensing engines use from 30 to 50 lbs. of steam per shaft h.p. (in the coal raised) per hour. For high-pressure engines and unfavourable conditions the consumption increases to about 100 or 120 lbs., and occasionally more.

TABLE SHOWING STEAM CONSUMPTION OF WINDING ENGINES.

(*W. C. Mountain.*)

Tests of a cross-compound non-condensing engine at Sherwood colliery gave a steam consumption of 40 lbs. per S.H.P. hour. The engine cylinders were 32 ins. and 53 ins., stroke 66 ins., pressure 125 lbs. per sq. in., superheat 65° F.

For the steam consumption of turbines *see* Part IV. Steam Turbines, page 1832.

The Indicator.

The function of the engine indicator fig. 6, p. 1770, is to produce a diagram which shall show with reasonable accuracy the pressure in the cylinder in relation to the position of the piston in its stroke. Usually the diagram is drawn on a paper wrapped round a drum, which is reciprocated by means of a cord attached to a reducing mechanism driven by the engine, so that the motion of the paper is a copy on a reduced scale of the piston motion. The pencil which draws the diagram must move parallel to the axis of the drum, so that its distance from a datum line represents the pressure in the cylinder.

For very high speeds, special forms of indicator, in which the diagram is traced out by a spot of light, and recorded photographically, are used.

The Crosby Indicator.

This indicator (sold by *Crosby Valve and Engineering Co., Ltd.*, 11–12 Foley Street, London, W. 1) has been designed for use with engines, either steam, gas, or oil. Fig. 2 shows the Crosby

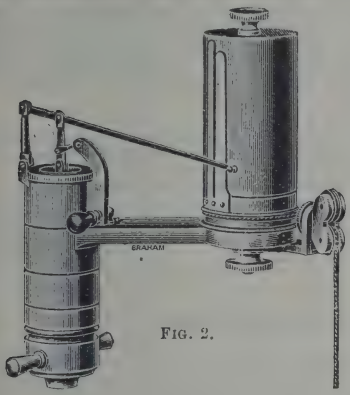

Fig. 2.

Fig. 3.

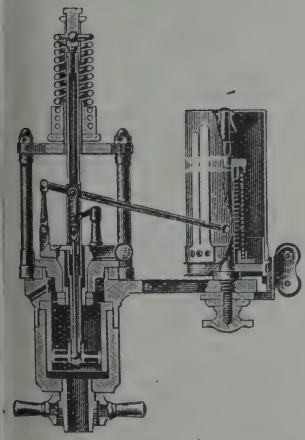

Fig. 4.

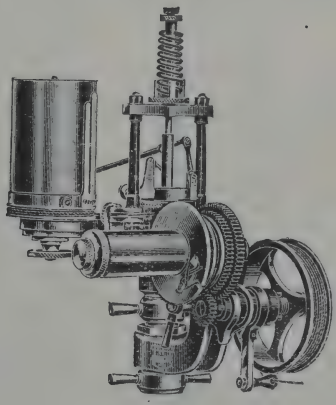

Fig. 5.

Indicator as ordinarily made, having a drum 1½ ins. in diameter, this being the correct size for high-speed work, and answering equally well for low speeds.

The special feature in the indicator is the use of a double-coil spiral spring, very carefully calibrated; this form of spring, which is shown in fig. 3, enables the strains to which it is subjected to be transmitted from the centre of the piston through a ball-and-socket joint. Each spring is made of a single piece of wire wound from the middle into a double coil, the ends of which are screwed into a head with four wings having spirally drilled holes to receive and hold them securely in place. Adjustment is made by screwing the spring in or out of this head until it is exactly of the right strength, when it is firmly brazed.

Fig. 4 shows a sectional view of the Crosby New No. 2 Indicator. This has the spring mounted outside the cylinder, where it is easily detached and replaced, and where it is removed from any effect of heat—a very necessary precaution when the indicator is used with superheated steam, or on gas engines. Another novel feature in this indicator is the shape of the piston. It is in form the central zone of a sphere, an arrangement which practically eliminates cylinder friction. The piston is connected to the pencil mechanism by a rod terminating in a ball-and-socket joint in the centre of the piston. The position of the pencil lever on the drum can be altered by screwing the spring up or down and locking it in place.

For the purpose of making the indicator of the utmost value to engineers, the Crosby New 'Continuous Drum' has been designed, and this apparatus makes it possible to obtain a series of diagrams on a roll of paper. The latest form has a novel arrangement, allowing the period between each diagram to be altered at will; the diagrams can be taken close together or farther apart as desired, and the roll supplied is 12 ft. long. Such an apparatus is of great value in ascertaining variations of load in electrical tests, and in connection with rolling and winding engines.

Another useful device, which saves having a reducing apparatus added to an engine, is the Crosby 'Reducing Wheel.' This gives a perfectly correct reduction of the stroke of any engine to the stroke of the indicator drum, and it is connected directly to the indicator and mounted on the indicator cock. The arrangement is portable and can be used on any engine.

The latest pattern includes a detent device which enables the indicator to be stopped to put on a fresh card without disconnecting the reducing wheel from the engine crosshead. See fig. 5.

To take an Indicator Card.

See that the indicator is in good order, the piston clean and free in the cylinder, all joints in the pencil gear free yet without slack. The pencil should fall by its own weight when the indicator is assembled without a spring. The spring should be chosen with reference to the pressure range, so as to give a diagram about 1¼ ins. high, or less still if the speed is high. (At very low speeds a lighter spring may be used and a larger diagram obtained.) Assemble the indicator, and see that the spring is properly secured at both ends without any slack. Couple the indicator to the cock F. Adjust the length of cord connecting the indicator drum to the reducing gear, so that there is no knock or slack at either end of the motion of the drum. At high speeds the tension of the drum spring should be considerable, so as to minimise variations in the tension of the driving cord.

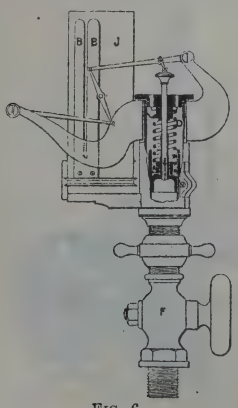

FIG. 6.

Fasten the paper on the drum J by means of the clips BB. Draw the atmospheric line by pressing the pencil lightly on the paper and pulling the drum round by the cord.

Adjust the pencil stop so that the pencil cannot be pressed too hard on the paper. The pencil point must be kept smooth and fine. A clear, fine line will thus be drawn without excessive friction between pencil and paper.

Connect the driving cord to the reducing gear, open the indicator cock, and after allowing steam to blow through for a few seconds, apply the pencil to the paper and allow it to remain in contact for a few revolutions and then withdraw it.

Shut the cock, disconnect the cord and remove the paper with the indicator diagram.

Mark the card with a reference number and write on it the particulars of speed, pressure etc., unless these are separately logged.

Indicator Piston.

In any indicator the piston should always fit the cylinder loosely enough to allow the steam to blow by it. This is very important, whether the instrument is used at high or low speeds. In regard to any errors that may result from leakage by the piston, it should be distinctly understood that leakage, unless it be sufficient to add to the atmospheric pressure above the piston, cannot affect the accuracy of the indications. Absurd devices have been even patented for keeping the piston tight, while the one thing needful is absolute freedom of motion.

In order that leakage past the piston may not accumulate pressure above the piston, the space above the piston must be in free communication with the atmosphere.

Indicator Connecting Pipes.

In general, short direct connections are preferable.

The use of a long connecting pipe may cause quite an appreciable addition to the clearance volume of a cylinder, especially in the case of small engines. Where, however, the connecting pipe has a bore of $\frac{5}{16}$ in. or $\frac{1}{2}$ in., as is usual, and suffers no contraction up to the indicator tap, and the speed is moderate, there is no appreciable error in the diagrams due to the connecting pipe being even 4 feet long, provided the bore of the two-way cock is quite $\frac{3}{8}$ in.; a bore of $\frac{3}{16}$ in. only may introduce serious error.

(*T. B. Morley*, '*Trans. Inst. E. and S.*,' 1914–15.)

THE INDICATOR DIAGRAM.

General Definitions.

The Atmospheric Line, AB, fig. 7, is a line drawn by the pencil of the indicator when the connections with the engine are closed and both sides of the piston are open to the atmosphere. This line represents on the card the pressure of the atmosphere, or zero gauge pressure.

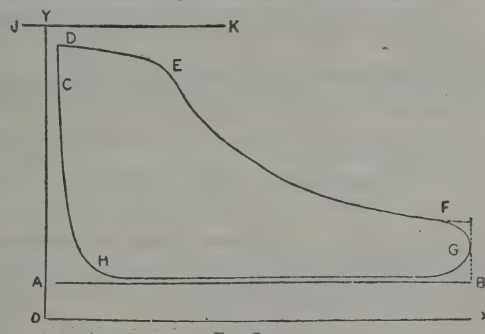

FIG. 7.

The Line of Absolute Zero Pressure, OX, is a reference line usually drawn about 14·7 lbs. by scale below the atmospheric line. It represents a perfect vacuum, or absence of all pressure.

At any considerable height above sea level the line OX becomes nearer the line AB.

The Clearance Line, OY, is another reference line drawn at a distance from the end of the diagram equal to the same percentage of its length as the clearance volume is of the piston displacement. The distance between the clearance line and the end of the diagram represents the volume of the clearance and of the ports and passages at the end of the cylinder.

The Line of Boiler Pressure, JK, is drawn parallel to the atmospheric line, and at a distance from it by scale equal to the boiler pressure shown by the gauge. The difference in pounds between it and DE shows the loss of pressure due to the steam pipe and the ports and passages in the engine.

The Admission Line is in two parts, CD, which show the rise of pressure due to the admission of steam to the cylinder by opening the steam valve (if the steam is admitted quickly when the engine is about on the dead centre this line will be nearly vertical), and

DE, which is drawn when the steam valve is open and steam is being admitted to the cylinder.

The Point of Cut-off, E, is the point where the admission of steam is stopped by the closing of the valve. It is difficult to determine the exact point at which the cut-off takes place. It is usually located where the outline of the diagram changes its curvature from convex to concave.

The Expansion Curve, EF, shows the fall in pressure as the steam in the cylinder expands and does work.

The Point of Release, F, shows when the exhaust valve opens.

FG represents the change in pressure that takes place when the exhaust valve opens; exhaust continues to the point H.

The Back Pressure Line, GH, shows the pressure against which the piston acts during its return stroke. On diagrams taken from non-condensing engines it is either coincident with or above the atmospheric line, as in fig. 7. On cards taken from a condensing engine, however, it is found below the atmospheric line, and at a distance greater or less according to the vacuum obtained in the cylinder.

The Point of Compression, H, is the point where the exhaust valve closes. It cannot be located very definitely, as the change in pressure is at first due to the gradual closing of the valve.

The Compression Curve, HC, shows the rise in pressure due to the compression of the steam remaining in the cylinder after the exhaust valve has closed.

The Mean Effective Pressure (M.E.P.) is the mean net pressure urging the piston forward.

The Initial Pressure is the pressure acting on the piston at the beginning of the stroke.

The Terminal Pressure is the pressure above the line of perfect vacuum that would exist at the end of the stroke if the steam had not been released earlier. It is found by continuing the expansion curve to the end of the diagram, as in fig. 7.

Defects in Diagrams.

A very common and serious defect in diagrams arises from the stretching of the indicator cord. If two diagrams taken from the same engine at the same time show noticeably unequal lengths the cords are probably inaccurate. As a rule the stretch is greatest when the drum is pulled open. Thus one end of the diagram is widened and the other narrowed, giving incorrect M.E.P. and points of valve action.

The cord used should be as short and as inextensible as possible.

The reducing gear should give an accurate copy of the motion of the engine crosshead, and the cord from the reducing gear should run in a direction parallel to the line of motion of the crosshead.

If the diagram is very much to one side of the card, and if the near end is quite straight and vertical, the drum is probably hitting its stop at one end of its travel. Alter the length of the indicator cord.

If the expansion line is stepped in rough terraces the indicator piston is probably sticking and the M.E.P. is too high.

If the expansion is wavy the spring is too light and should be replaced by a stiffer one.

Mean Effective Pressure.

This is best determined by finding the area of the indicator diagram; dividing this by the length, so obtaining the mean height; then, multiplying the mean height by the pressure scale the mean effective pressure is the result.

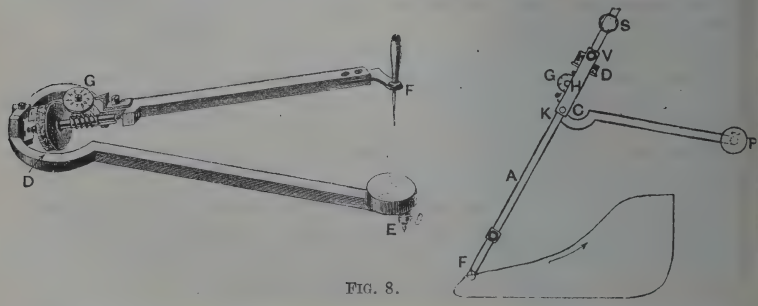

FIG. 8.

The best method of measuring the area of the diagram is to use a planimeter, which if carefully handled gives results accurate to hundredths of a square inch.

The most commonly used planimeter is of the Amsler type, and is shown by fig. 8.

It consists of two arms hinged together; one is constrained to swing round a fixed pivot, the other carries a tracing point which is made to follow the outline of the diagram. This arm also carries a roller, with its axis in the centre line of the arm, and provided with a scale and vernier by which its rotary movements can be accurately measured. As the tracing point moves round the diagram the roller partly slides and partly rolls over the paper or board on which the diagram is drawn or to which it is pinned. The readings of the scale before and after each exact circuit of the diagram are noted; their difference measures the area of the diagram on a scale determined by the proportions of the instrument.

The roller should be pivoted so as to rotate freely, but without endshake, and the surface on which it moves should be flat and unglazed. The position of the pivot point should be chosen so that the tracing point can reach freely all parts of the outline. The pivot point has a needle which can then be pressed into the paper or board.

It is advisable to check the planimeter occasionally by running it round a simple figure, such as a square or circle, the area of which can be easily calculated independently.

To Calculate the Horse-Power of an Engine.

P = M.E.P. (mean effective pressure) on piston, in lbs. per sq. in.;

A = net piston area in sq. inches. (The net area at the crank end of the cylinder = area of cylinder less area of rod. If there is a tail rod at the end remote from the crank, A = cylinder area less area of tail rod.);

L = length of stroke in feet;

N = revs. per minute.

Then the I.H.P. developed on *one side* of the steam-engine piston $= \frac{\text{PLAN}}{33{,}000}$

For a double-acting steam-engine, the I.H.P. developed in the cylinder $= \frac{2\ \text{PLAN}}{33{,}000}$, where P, A, are the mean M.E.P., and mean area for the two cylinder ends.

More exactly I.H.P. $= \frac{(P_1A_1 \times P_2A_2)\ LN}{33{,}000}$,

where P_1, P_2, A_1, A_2, are the pressures and areas for the two sides respectively.

For a gas engine (single acting, single cylinder) the I.H.P. $= \frac{\text{PLAE}}{33{,}000}$, where E = explosions or impulses per minute, and depends on the cycle and governing system as well as on the revs. per minute.

For a double-acting steam-engine cylinder

$$\text{I.H.P.} = \frac{\text{PAS}}{33{,}000}, \text{ where S = piston speed in ft. per minute, since S = 2 LN.}$$

Approximate Steam Consumption, from the Indicator Diagram.

Draw a horizontal (constant pressure) line on the diagram so as to cut the expansion line and compression line (or compression line produced, if necessary) at a pressure just above release (exhaust opening).

If

u = volume in cu. ft. of one lb. dry steam at the pressure of this horizontal line;

a = length of horizontal line between expansion and compression lines;

b = length of stroke of diagram;

then

$$\text{Lbs. dry steam on diagram per i.h.p. hour} = \frac{13{,}750\ a}{\text{M.E.P.}\ b\ u}.$$

This is often referred to as the theoretical or 'indicated' steam, the actual being less or greater according to the degree of superheat, jacketing, leakage, etc. Hence the theoretical consumption must be *divided* by a factor (which is approximately the dryness fraction at exhaust opening).

For a compound engine first find the 'indicated' steam consumption for either cylinder as above; then for the whole engine, multiply by the i.h.p. of that cylinder and divide by the i.h.p. of the engine. This result divided by the steam consumption factor gives the probable actual steam consumption of the engine.

STEAM CONSUMPTION FACTORS.

Cylinder.	H.P.	L.P.
High superheat	1·0 –1·1	0·8 –1·0
Moderate superheat	0·9 –1·0	0·75–0·95
Saturated steam	0·8 –0·85	0·7 –0·75
Badly clothed, saturated steam	0·65–0·75	0·6 –0·7

To Interpret the Indicator Diagram.

Besides the calculation of horse-power and the rough estimate of steam consumption, from the diagram, other important information can be learned from a study of the diagram, as follows :—

The diagram will show the opening and closing of the valves, as explained on p. 1771, fig. 7. If the point of cut-off is fixed, as with most slide and piston valve engines, the depth of the steam admission line DE below the boiler pressure line YK is a measure of the loss by throttling. If this is invariably considerable, it may pay to shift the eccentric so as to give an earlier cut off. With a simple slide or piston valve this would make the exhaust open earlier and the compression commence earlier. These, and particularly the latter, must be watched, as too early compression sends the compression pressure above the steam chest pressure. This is not good; although the compression line should rise nearly to the admission pressure. In the case of a reversing engine having a Stephenson, Joy, or similar link motion, the point of cut-off is varied by shifting the equivalent eccentric; and thus at early cut-off the exhaust and compression are both early, but at late cut-off the exhaust and compression both become late. Hence when studying such diagrams these changes of exhaust and compression with cut-off must always be kept in mind. The points of valve action can also be altered by changing the lap. Thus if the exhaust edge of the valve is chipped the exhaust takes place earlier and the compression later. Similarly chipping some of the lap off the steam edge of the valve makes the cut-off later and lead earlier.

If the admission line DE falls rapidly, the valve is too small or the valve travel too small.

In a multiple-cylinder engine the diagrams give the distribution of power and forces among the several cylinders. As a rule these should be roughly equal for the several cranks, but need not be equal for the two cylinders of a tandem engine. Indeed, in the latter case, the h.p. cylinder may with advantage take rather more than half the load if the steam is superheated.

Valve setting should always be checked by actual indicator cards after an engine is first started to work.

It is found in practice that the expansion line (fig. 7, p. 1771) is closely hyperbolic when using saturated steam, the two axes of the hyperbola being the absolute zero line OX and a vertical touching the diagram at CD. Hyperbolic curves can be purchased printed on transparent paper for placing over indicator diagrams. If the expansion line rises above the hyperbola as the pressure falls it indicates leakage past the steam valve into the cylinder. Similarly, if the expansion line falls more rapidly than the hyperbola it indicates either leakage past the exhaust valve out of the cylinder, excessive condensation of steam in the cylinder, or the use of initially superheated steam. If superheated steam is used, the vertical axis of the hyperbola should be about the clearance line OY in fig. 7; but the exact position depends on the degree of superheat.

The hyperbola is easily drawn more or less completely as desired when it is remembered that the absolute pressure multiplied by the volume has the same value at all points on the same hyperbolic curve.

ENGINE TYPES FOR VARIOUS DUTIES.

Each type of engine has a field, not sharply defined, in which it shows to best advantage.

Elaborate and expensive types are least desirable when coal is very cheap, the working hours few, labour unskilled, or the working conditions very rough.

Non-condensing engines consume from 20 to 50 per cent. more steam and coal than condensing engines.

Unless floor space is limited or very high speeds are desired, a horizontal engine is generally more satisfactory than a vertical. It is cheaper to install and more accessible for running and overhauling.

Steam turbines are relatively uneconomical in very small units. In the neighbourhood of 1,000 to 1,500 horse-power they surpass the best reciprocating engines, and for very large units—unless for some special purpose, as driving a reversing rolling-mill—are without serious rival. To show to advantage a turbine must be run condensing, with a good vacuum.

Where economy is at all important the ordinary simple (single-expansion) engine is at a marked disadvantage, which, however, is least with steam superheated 120° or 150°F. For most purposes the compound is the standard type, although the uniflow (a special form of single-expansion engine) is widely adopted. Triple and quadruple expansion engines are more economical than compound, but are more costly and complex. They are therefore chiefly employed on ships, for towns pumping, flour mills, and other situations where coal consumption is specially important. Their superiority over the compound engine is reduced if the steam is superheated.

The class of engine is frequently designated by the valve gear. Thus the plain slide valve gives the cheapest engine and also, other things being equal, the least economical.

The piston valve is really a circular slide valve, and gives an engine of similar characteristics. For the highest economy and class of engine Corliss or drop valves are desirable. The Corliss valve is really a circular slide valve of small diameter which rotates to and fro through a small angle in its valve chamber. The drop valve may be of the double-beat seating type or of the double-beat piston type. As a rule Corliss and drop valves are operated by a trip valve gear or other form of valve mechanism enabling the cut-off to be automatically varied to suit the load. Slide and piston valves, on the other hand, are not so suitable for cut-off governing and are not usually so arranged, but rely on throttling the steam to meet changes of load. High-speed engines almost invariably have piston or slide valves, because trip and other cut-off gears are unsuitable at high speeds of revolution.

Cut-off, or expansion, governing gives the best economy for variable loads, except at very light loads, when throttling is superior. The difference is least with highly superheated steam, which tends to equalise the steam consumptions at different loads (measured per horse-power, of course).

The superior economy of Corliss and drop valve engines is often believed to be due to the superior qualities of trip valve gears. Actually this is a very minor factor. The chief gain arises from the fact that the inlet and exhaust ports and valves are usually quite separate.

The following list shows the engine types frequently adopted for various duties :—

Duty.	*Type of Engine.*
Agriculture, occasional service	Simple, slide or piston, N.C.
„ regular service	Compound, slide or uniflow, N.C.
Cement works	Compound, Corliss or drop, uniflow, turbine, S.
Electric generating, small	Compound, high-speed vertical, Corliss, or drop, S.
„ „ medium	Compound, Corliss or drop; uniflow; or turbine, S.
„ „ large	Turbine, S.

Duty.	*Type of Engine.*
Factories, cotton mills, etc.	Compound, Corliss or drop, uniflow, geared turbine, S.
Flour mills	Compound or triple, Corliss or drop, uniflow, S.
Paper mills	Compound, Corliss or drop; uniflow, turbine, also with steam extraction, S.
Portable	Same as agriculture.
Pumping, centrifugal	Compound, usually high-speed vertical, also uniflow if at moderate speed, S.
,, hydraulic and town water	Triple three-crank vertical, slow-speed, Corliss or drop, S.
,, well pumps	Compound or triple, Corliss or drop, S.
Rolling mills, not reversing	Horizontal compound, Corliss or drop, uniflow, S.
,, ,, reversing	Two- or three-crank, piston valves, simple or tandem compound, often N.C., S.
Winding	Two-crank simple or compound (tandem usually), N.C., S.

Note.—N.C. indicates non-condensing. S. indicates superheated steam.

Engine Types, General.

As coal increases in price the general tendency must be towards the more efficient engines. Thus, for agricultural, portable, and other 'occasonial' engines, superheated steam is highly desirable. Condensation is often difficult to arrange, and this makes the merit of the uniflow engine less pronounced. Compounding does not add very much to the cost and justifies itself where the total hours worked in the year reaches a reasonable figure.

For factory working, a high-class compound or uniflow engine or turbine is essential and the steam should be superheated 100 to 150° F.; similarly for electric generation, other than occasional or intermittent use.

For large electric generating sets the steam turbine alone need by considered, and should use high pressure and high superheat.

For rolling mills and winding engines a fairly high degree of superheat, 100 to 150° F., is advisable. If non-condensing the exhaust steam should be utilised in a low-pressure turbine. If this is not convenient, condensation should be employed, although it is not yet usual. In that case compounding should be adopted.

The Uniflow Engine.

The special characteristic of the uniflow engine is that the steam is exhausted through a central ring of ports; the piston has a length about 90 per cent. of the stroke, and uncovers the exhaust ports at about 90 per cent. of the working stroke (see fig. 9). The steam enters by inlet valves, usually of the double-beat seating type, placed at the cylinder ends, and, as it leaves at the middle, the inlet ends are never cooled by exhaust steam rushing over their surfaces, nor are the exhaust ports exposed to live steam. The clearance volume is 2 to 3 per cent. of the stroke volume, and compression normally begins when the piston covers the exhaust ports—*i.e.* at about 10 per cent. of the compression stroke.

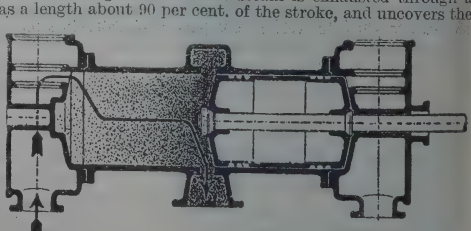

Fig. 9.

The high compression serves to heat not only the clearance surface, but the piston face, and condensation during admission is reduced to a minimum. Cyclic temperature changes in the cylinder walls are reduced, and the temperature falls gradually from the ends to the exhaust belt.

The entire expansion takes place in one cylinder, hence early cut-off is necessary.

The number of expansions is usually about 10; that is, about 10 per cent. cut-off. This is not quite so high a figure as for a typical compound engine, but owing to the absence of receiver losses and reduced initial condensation, a better economy by 5 to 10 per cent. is obtained with the uniflow, if condensing.

The full steam pipe pressure comes on the large piston, and the load on the line of parts is high in proportion to the M.E.P. This makes for weight and cost, but higher unit stresses, if based on steam pressure only, are permissible if due advantage is taken of the heavy reciprocating parts and high rotational speed to give a high inertia loading. The uniformity of turning is then equal to that of a good tandem compound engine, but is inferior at low rotational speeds.

Owing to the high compression ratio, if the vacuum falls below normal, the pressure at the end of compression would become excessive unless an efficient preventive device ('compression release gear') were provided.

The Galloway Uniflow Engine.

(Galloways, Ltd., Manchester.)

The steam valves are double-seated drop valves, and are placed in the cylinder covers, which form steam jackets for the valves and cylinder ends. In boring the cylinder, allowance is made for the higher temperature, and consequent greater expansion, at the ends when working. The cylinder is provided with an inspection door, by removing which the piston rings and cylinder bore may be inspected.

The novel features of the engine described are the patent shockless high-speed valve gear and the automatic compression release gear. In this valve gear (fig. 10A) oil under pressure is

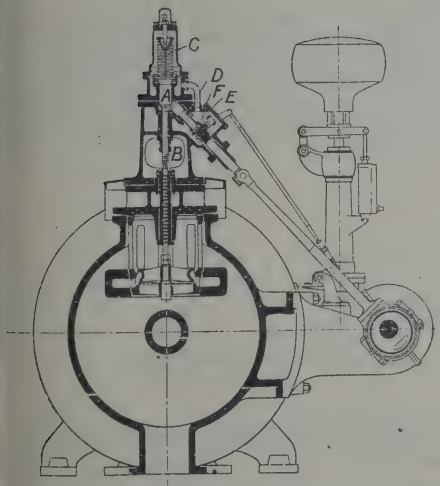

FIG. 10.—Cross Section of Cylinder.

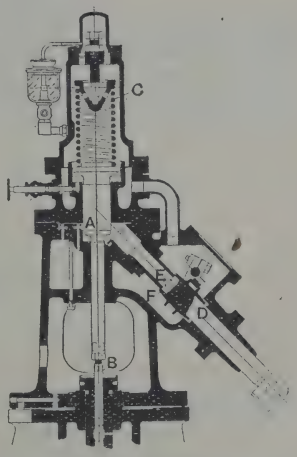

FIG. 10A.—Arrangement of Oil Valve Gear.

applied below the plunger A connected to the valve spindle B and lifts the valve. An eccentric on the lay shaft operates the ram D of an oil pump in the valve bonnet. The ram is hollow, and has a ring of slots or ports E, which at certain parts of the travel may be covered by a sleeve F, the position of which is controlled by the governor. On the upstroke of the pump oil is forced into the chamber below the plunger, thus raising the plunger and the steam valve. At a point determined by the position of the governor, the ports in the hollow ram are overrun by the sleeve and the oil escapes. The valve is then free to close under the combined

action of a spring and dashpot. The valve gear is silent, compact, and takes little power to operate it.

The automatic compression release gear is shown in fig. 11. Two supplementary exhaust valves G, H, are arranged on the side of the cylinder. They are normally kept closed by springs J, K. On the engine lay-shaft is a sleeve L carrying two cams of tapering form, which are capable of longitudinal movement. Their axial position is made to correspond automatically with the vacuum by means of the spring-controlled piston O of a small cylinder P at the end of the lay-shaft, one end of this cylinder being in communication with the condenser. The

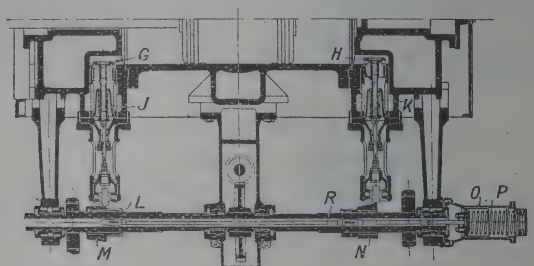

FIG. 11.—Arrangement of the Automatic Exhaust Gear.

piston operates the cams by the rod R. At normal vacuum the small end of each cam is just clear of the roller on the valve stem, and the valves are not opened. If the pressure in the condenser rises the cams move axially, so that each exhaust valve is opened during part of the compression stroke, the amount and duration of the opening depending on the cam position, and hence on the vacuum. This engine starts without vacuum, as it drives its own air pump, and the compression release gear gives full relief of compression until a vacuum is established, and then permits the compression to increase until at normal vacuum full compression is reached. Fig. 12 shows the operation of this gear.

FIG. 12.—Indicator Diagrams, showing Operation of Compression Release Gear.

THE PAXMAN POSITIVE VALVE GEAR ENGINE.

The Paxman type of engine is chiefly noticeable for its simple positive valve gear, its high rotational speed, massive construction, and silent running, its sensitive inertia governor, frictionless metallic packing, and also for its low steam consumption, a result of under 10 lbs. per i.h.p. hour being obtainable under favourable working conditions.

With the Paxman valve gear, fig. 13, no dashpot is used. The valve is raised by the cam lever A, acting upon the roller B, this lever being moved by the eccentric, and the whole movement is accomplished without noise or hammering. The roller B is always kept in close contact with the cam or lever A during the travel of the valve, by means of the spring shown in the

bonnet. The cam does not move clear of the roller until after the valve is seated, and consequently, even when the engine is running at the highest speeds, the gear is entirely silent. The friction to which the valve is exposed is practically nil.

There is no tripping movement with the valve gear, but the valve is lowered gently on to its seat by means of the cam (the profile of which is so shaped as to allow this to be done rapidly) and when the valve is seated, and not until then, the cam moves clear of the roller. The system renders quite permissible the employment of such high piston speeds and revolutions (even in the case of very large engines) as could not be possible with trip-gear.

The valves are free to lift easily in the case of any abnormal pressure arising within the cylinder, and they thus act as relief valves, avoiding all danger of water shock.

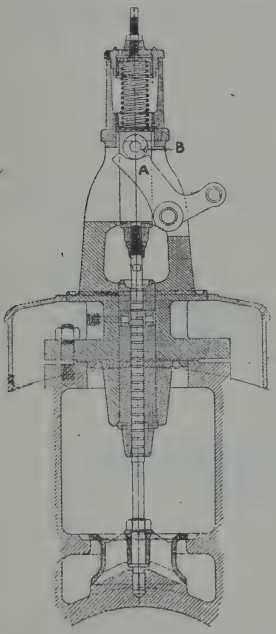

FIG. 13.

The valve spindles are grooved and work in cast-iron sleeves; by means of the Paxman system of draining, no stuffing boxes are required, which reduces the friction to a minimum, and allows the governor to be extremely sensitive while having great stability.

The governor is of the inertia type, and is placed on the side shaft: it is directly connected to the two high-pressure steam eccentrics, which eccentrics are movable on a slide block keyed to the shaft: thus the governor can alter the eccentricity, and consequently the cut-off. It regulates within an exceptionally short period, and the momentary change of speed due to the load being thrown on or off is only slightly in excess of the permanent change. Fig. 14 shows graphically the very slight alteration in speed occasioned by throwing the load suddenly off or on the engine, the resultant change of speed being hardly perceptible. The action of the Paxman governor is immediate, and it combines extreme sensibility with a perfect stability comparable with the best turbines.

Fig. 15 shows the piston-rod packing of the Paxman effective type. By eliminating springs, friction is reduced to a minimum, and as the packing is free from wear, perfect steam

tightness is assured. The packing consists of a series of cast-iron rings which fit over the rod, and are held in cast-iron boxes which allow them to oscillate sideways, thus avoiding friction between rod and rings. There is no gland bush, the steam having direct access to the packing, but it returns to the cylinder during the period of expansion, instead of leaking through the packing. The rings form a series of chambers which are efficiently drained, any steam escaping

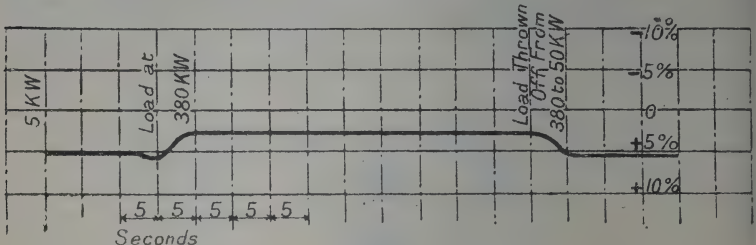

FIG. 14.

from the front chamber entering the second chamber, and there expanding. A small part of it may escape to the third chamber and undergo further expansion, and so on, but the last ring will never show the slightest leakage.

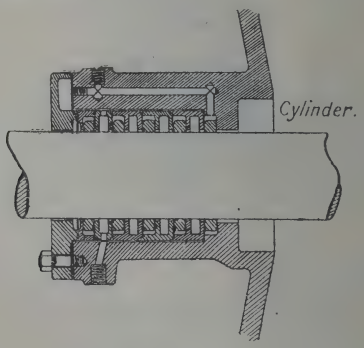

FIG. 15.

Paxman engines are made of the single-cylinder coupled compound, or tandem compound horizontal types, and for any steam pressure up to 190 lbs. at the engine stop valve.

The Paxman Positive Valve Gear lends itself to the easy conversion of existing engines to Paxman-Lentz type. In actual practice, improvements and economies in steam consumption up to 26% have been obtained with a great reduction in maintenance expenses.

ROBEY DROP-VALVE REVERSING AND OVERWINDING GEAR FOR WINDING ENGINES.

(Patent.)

The distinguishing feature of this gear, fig. 16, is its simplicity combined with absolute efficiency.

Both steam and exhaust valves are actuated by the one eccentric marked A. This is effected by the rod B actuating the rocking lever C, which is supported on a fixed bearing **D**, giving an up-and-down motion to the steam actuating lever E, and the exhaust lever F; the latter, by means of the bell crank lever G, opening the exhaust valve at the proper moment.

The steam admission rod E by means of the well-known Robey trip-motion opens the steam valve. The rods E and F have a constant movement, and the reversing is done by varying the

position of the rod B. This is effected by moving the eccentric A (the strap and connections are omitted in the figure). This eccentric is mounted on a square block H, which is driven from a fixed plate on the layshaft.

By means of the sliding sleeve on the layshaft, and two bell crank levers, the eccentric A can be moved to the position indicated by the dotted lines, and the engine will then run in the opposite

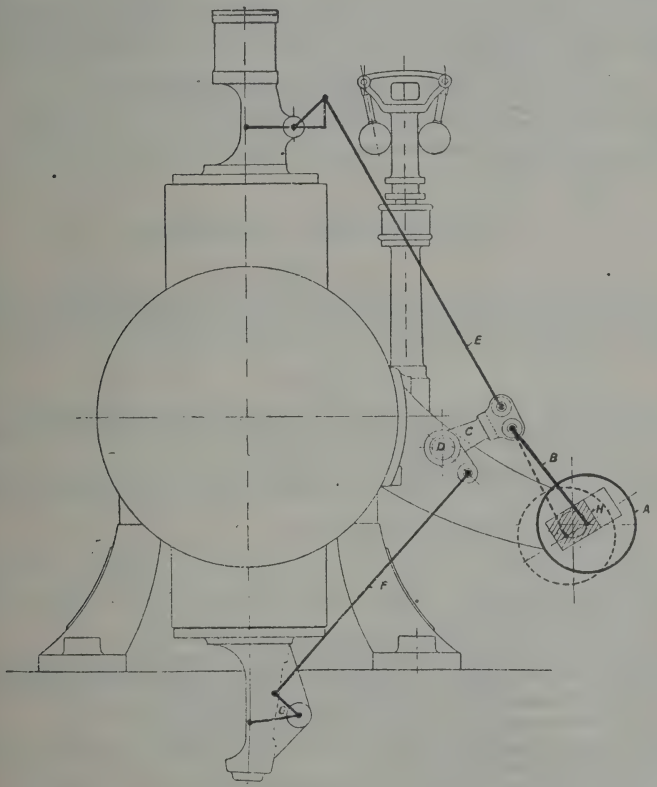

FIG. 16.—Robey Drop-Valve Reversing Gear.

direction. The sliding sleeve is connected by a simple fork connection to the reversing lever and the power necessary to move this eccentric A is very small indeed, and the lever can be worked by hand in engines up to the largest sizes.

Each end of the cylinder has an exactly similar arrangement of the gear, and the same sliding sleeve actuates both eccentrics.

When it is desired to have the gear under the control of the governor, and not by hand alone, it is necessary to have a small auxiliary eccentric on the layshaft, which is keyed on in a fixed

position, and does not vary with the direction of running of the engine. This auxiliary eccentric, in conjunction with the governor, regulates the exact cut-off in accordance with the speed of the engine.

When the governor is in the lowest position, the cut-off is at the maximum, and the driver has therefore only to turn full steam on at the commencement of the wind, as the governor will cut off the steam when maximum speed is obtained. The connection of the governor to the gear is automatically thrown out of action when the engine is reversed, thus enabling the driver to put full steam against the engine.

The steam admission valves are of the well-known Robey type, and there is no liability whatever for the valve to hold up. As a measure of precaution, however, an arrangement is fitted which closes the valve positively if it should by any means not fall, but this has never been known to come into action.

Indicator diagrams show that the lead at all points is practically constant.

In the patent overwinding gear the steam is shut off immediately at the cylinder instead of at the throttle; this renders the system particularly effective.

The overwinding gear is absolutely part of the valve gear, and has not to be driven by an independent chain or gearing of any description.

The Robey High-Speed Vertical Engine.

(Open Type.)

Figs. 17, 18 show the latest type of high-speed vertical engine with open front. It is fitted with the Robey improved crankshaft throttle governor driven direct from the crankshaft without either gearing or belt, thus ensuring absolute reliability. The flywheel can be supplied either suitable for belt driving or of the disc type suitable for direct coupling.

Specification.

Cylinder is made of the best cold-blast iron, free from all defects, fitted with bright covers secured by studs and nuts. All stuffing boxes have gunmetal neck bushes and gunmetal glands. Cylinder drain cocks are fitted with copper-pipe connections.

Governor is of the crankshaft throttle type, dispensing with either belts or gearing for actuating governor. The speed of the engine can be varied while running by means of the adjusting arrangement fitted on the governor.

Piston is of cast iron fitted with expanding rings.

Piston Rod is of steel, coned at top end, fastened to end of piston by nut and pin, and forged solid with crosshead.

Crosshead is of forged steel, fitted with cast-iron slipper, with ample bearing surface and suitable means of adjustment.

The gudgeon pin is of case-hardened tough mild steel ground up true.

Connecting Rod is of best mild steel finished bright all over, fitted with marine large end, and small end provided with adjustment. The top is fork ended and with gudgeon pin shrunk in.

Valve Rod is of best mild steel with case-hardened eye adjustable by a small cotter.

Crankshaft is of steel turned all over and of the balanced slab type.

Standard is of special design with open front, securely attached to baseplate and cylinder, and has a removable polished pillar in front.

Crosshead Guide is tooled out perfectly true, and well fitted with oiling arrangements.

Base Plate and Bearings.—The cast-iron base plate has two adjustable bearings, fitted metal to metal, resting in bored-out carriages formed in base plate and secured by cast-iron caps, with brass and glass needle or drop-feed lubricators.

Flywheel is provided of a heavy pattern, accurately balanced, and turned on face for driving belt, or of the disc pattern with facing for direct coupling to dynamo as required.

Oiling Arrangements.—A special oil reservoir is provided at the top of engine standard with connecting pipes to all working parts.

The crank chamber is formed to collect the oil after use, which may be drawn off by means of a small cock provided at the bottom of the engine bedplate. Suitable splash plates are provided.

Extended Bedplate.—This can be made of suitable design to suit any make of dynamo.

THE GALLOWAY DROP PISTON VALVE ENGINE.

(*Patent.*)

The special features of this engine (*Galloways Ltd.*) lie in the steam valves, fig. 19, which are of the drop piston type working in a slotted seat, which in turn is carried by a short vertical cylinder standing in the inlet valve of the steam chest. This short cylinder is surrounded on all sides by steam at one temperature and pressure, and remains truly circular under all conditions however much the steam temperature and pressure may vary. This preserves the circularity of the valve liner and therefore its steam-tightness.

The piston valve itself is of the double-beat type fitted with 'Duplex' spring rings. The duplex rings are so arranged that they cannot fall out of the body of the valve in case of breakage.

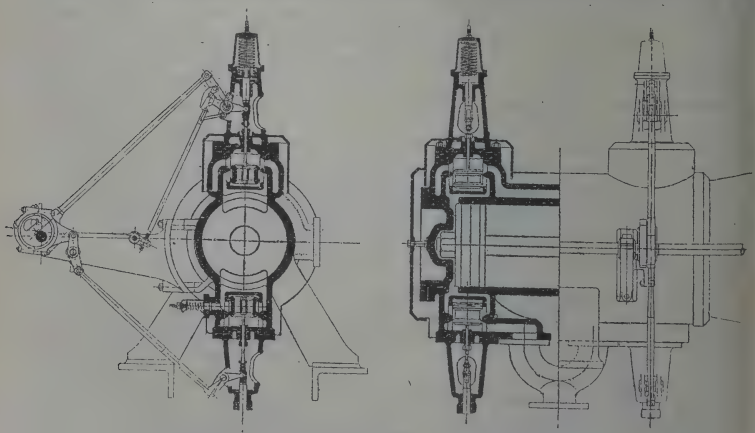

FIG. 19.—Sections through Cylinder, showing Drop Piston Valves.

There being two rings, one inside the other, bedded against each other over their whole circumference, the ring cannot be collapsed by the application of sudden pressure, as when the ring passes over a steam port. On test, the steam leakage in a 14-inch steam valve of this type proved to be a fraction of 1 per cent.

The Galloway Reversing Rolling Mill Engine.

In connection with the reversing rolling mill engines Messrs. Galloways fit a patent single lever expansion control gear. By the employment of one handling lever, both the throttle valve and the cut-off are suitably varied in a predetermined manner. This is so arranged that during the mean rolling period the engine works with variable cut-off and full steam pressure in the cylinders, thus securing maximum economy. When starting up, the gear partially closes the throttle and gives late cut-off so as to product an even steady turning at a slow speed. When the handling lever is brought to mid gear at the completion of a pass, the control valves are forcibly closed so that no steam leakage can take place. By means of this valve gear the steam consumption is claimed to have been reduced to one-half, or less, of that normally required, whilst the output of the rolling mill is increased, as the single lever expansion control gear gives very rapid action on the part of the engine.

Forced Lubrication.

Forced lubrication as a continuous or arterial system of conveying oil under pressure to all the working parts of an ordinary reciprocating engine was patented in 1890 (No. 7397) and introduced by Messrs. Belliss & Morcom Ltd. of Birmingham in their self-lubricating engine (*vide* sectional illustration, fig. 20, which shows their original design of compound engine 'O' type). The constant supply of oil under pressure prevents the working surfaces coming together, the film of oil taking an appreciable time to squeeze out, which is sufficient in a double-acting engine running at a high speed to last until the stress is reversed and the film on the other brass comes into operation; the bearing surfaces are thus prevented from coming into actual contact. In this system the engine is enclosed, and oil drawn from a reservoir in the bedplate by a pump is fed to circumferential grooves in each of the main bearings. The crankshaft is drilled, so that oil drawn from the circumferential grooves in the main bearings is conducted to similar circumferential grooves in the crankpins and thence to the crosshead pins and guides. The valve motion is lubricated in the same way, also the working joints in the governor. The oil escaping from the journals returns to the oil-well in the bed for re-use. The pump, which is of the oscillating type without loose valves or packings, is operated from the eccentric and draws its supply through a gauze strainer. The pressure of oil generally used may be anything between 10 and 25 lbs. per sq. inch.

The Belliss and Morcom 'O' Type High-Speed Engine.

The special feature of this engine, fig. 20, is the arrangement of the slide valves, requiring one eccentric and rod only. The low-pressure valve is superimposed above the high-pressure, working in the same valve chamber, the high-pressure valve taking steam on the inside and exhaustion direct to the low-pressure, which cuts off on the outside edge. The cranks are necessarily set opposite to each other, the steam being admitted simultaneously to the top of one cylinder and the bottom of the other, by which arrangement the reciprocating parts are to a great extent balanced, the stress on the bearings much reduced, and a high speed of revolution made possible. A variation of speed not exceeding 3 per cent. between full and no load can be guaranteed. The governor gear is arranged so that the speed of the engine is capable of being adjusted whilst running.

A modification of this design of engine, more recently introduced, is the 'V' type (see fig. 21, p. 1786).

BACK PRESSURE AND EXTRACTION ENGINES.

Increasing attention is now being paid to the saving of fuel, which is rendered possible by the combination of power supply and heating services, the heating being effected by using exhaust steam or steam taken from the engine at an intermediate pressure. Factories using steam for heating in their own industrial processes offer special opportunities in this direction, though schemes have also been successfully carried out in which the heating of adjoining offices and houses has been effected in addition to the heating required in the factory processes.

For example, in a factory requiring 200 i.h.p. for driving machinery, and 3,200 lbs. of steam per hour at about 5 lbs. per sq. in. gauge pressure for heating purposes, the methods of independent and combined supply may be compared as follows. In the independent method an economical condensing engine would be used, taking, say, 11 lbs. steam per i.h.p. hour, or $11 \times 200 = 2{,}200$ lbs. steam per hour. The total steam is thus $2{,}200 + 3{,}400 = 5{,}600$ lbs. per hour.

In the combined system, a back pressure engine would be used, exhausting at the pressure required for the heating steam. It would require, say, 18 lbs. steam per i.h.p. hour, or 3,600 lbs. per hour. Allowing 10 per cent. for loss by condensation, 3,240 lbs. exhaust steam per hour are available for heating. Thus the steam to be generated for all purposes is 3,600 lbs., as

Continued on page 1788.

NOTE.—The Power given in Columns 2 and 3 is the Brake Horse-Power; the Indicated Horse-Power will be correspondingly higher.

against 5,600 lbs. in the former case, and even though the whole of this steam has to be generated at high pressure and (preferably) superheated, the fuel consumption at the boiler is reduced in nearly the same proportion. The saving in fuel is thus $\frac{5,600 - 3,600}{5,600} \times 100 = 35{\cdot}6$ per cent. approximately.

By means of such systems the large proportion of heat carried away and lost in the condensing water of even highly economical power plants is greatly reduced; cases are on record in which the heat utilised as work in the engine, together with heat made available for heating purposes, amounts to 77 per cent. of the heat in the steam delivered by the boiler.

In the 'intermediate steam extraction' system, which is adapted for fluctuating power and heating requirements, a compound engine is used, the heating steam is taken from the receiver between the cylinders, and only a part of the steam used in the h.p. cylinder passes to the l.p. cylinder, and thence to the condenser. By means of a pressure regulator, the intermediate pressure is allowed to vary only between fixed limits. With an increased demand for heating

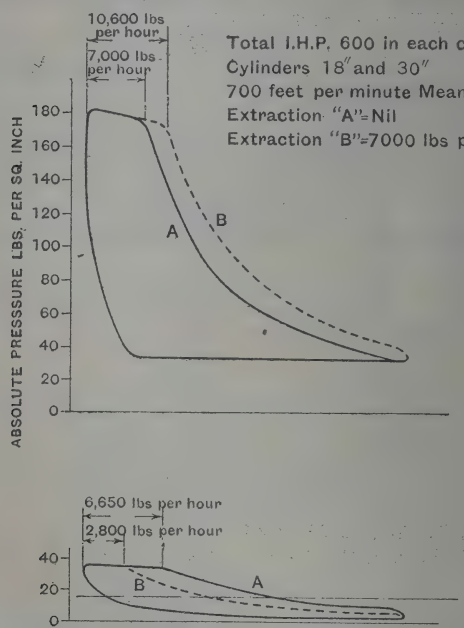

FIG. 21A.

steam, the pressure falls slightly, the pressure regulator makes the l.p. cut-off take place earlier, and, if the load on the engine remains unchanged, the speed governor makes the h.p. cut-off correspondingly later; thus more steam passes through the h.p. cylinder and less through the l.p. Provision is usually made for supplementing the 'extraction' steam, when necessary, by steam taken directly through a reducing valve from the live steam main; this additional supply is also controlled automatically. The l.p. cylinder may with advantage be of the 'uniflow' type (page 1776).

On account of the variations in the distribution of the power between the two cylinders with varying demands for extracting steam, the extraction engine usually has its cylinders arranged in tandem.

This is not, however, absolutely essential, and, particularly if the extraction steam is comparatively small in quantity, the engine may be of the cross compound arrangement.

Typical indicator diagrams for an extraction engine are shown in fig. 21A.

The steam quantities in each cylinder with and without extraction are marked on the diagrams, the total load being the same in both cases.

The Galloway Extraction Engine.

Fig. 21B shows a typical extraction engine as made by Messrs. Galloways Ltd., Manchester. It is of the tandem type, with a uniflow low pressure cylinder.

The inlet valves of both cylinders are of the double beat drop type and are operated by the firm's liquid valve gear (see p. 1777). The exhaust valves of the high pressure cylinder are piston valves, driven by eccentrics on the lay shaft through intermediate rocking levers.

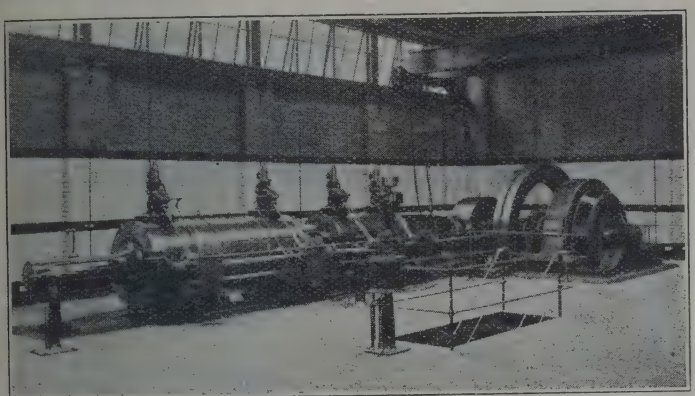

FIG. 21B.—The Galloway Extraction Engine.

The engine is totally enclosed, with forced lubrication to the cylinders and principa lparts and is in accordance with the best modern high-class practice.

The speed is controlled by a vertical spindle centrifugal governor, and the pressure of the extraction steam is adjusted and automatically maintained constant within fine limits by means of the pressure regulator which is seen in the foreground. The servo-motor which actuates the valve gear is in this instance below the floor; in other respects the pressure regulator is as described below.

The Galloway Steam Pressure Regulator.

(*Patent.*)

This Pressure Regulator, in the form suitable for use with an extraction engine, is shown in fig. 21C.

A pipe A conducts steam from the process-steam main through a strainer T and valve S to the interior of a closed cast-iron chamber C. The entrance of the steam to the chamber is controlled by a valve B, held closed by an adjustable spring D. The tension of the spring is so regulated that at the pressure desired in the main there is a slight escape of steam past the valve B, this steam emerging from the chamber C through an adjustable leak F to atmosphere.

The rod E controlling the valve B is of stainless steel, and, to avoid friction in operation, the right-hand end is finished to a thin strip, which is secured to a lug, and bends slightly as the rod moves. The end supporting the valve has a cup engaging the rounded end of the valve spindle. The whole mechanism is practically frictionless, and responds to the slightest variation in the pressure in the main.

The steam escaping from the valve B fills the chamber C at a pressure slightly above atmospheric owing to the throttling effect of the leak F. Any variation in pressure in the main will result in a corresponding change in the pressure inside the chamber. It is this latter variation which is made use of to operate the regulating mechanism.

In the chamber is a container H filled with mercury, which communicates through a hole K with a chamber J open to atmospheric pressure. In this chamber rides a cast-iron float L, frictionlessly guided. It will now be seen that a variation in the pressure in the chamber C will act on the surface of the mercury in container H, and cause the float L to rise or fall. This movement is communicated through a lever MN to a pilot-valve of normal type, operating an oil or

water-servo-motor, shown towards the bottom of the section. A rise of the float L will push the pilot-valve down, causing the servo-motor to be moved to the left; this movement will, however, raise the lever MN by the pin P, and restore the pilot-valve to its normal position. There is thus a definite position of the servo-motor for any given pressure in the chamber C. The servo-motor controls the cut-off in the low-pressure cylinder.

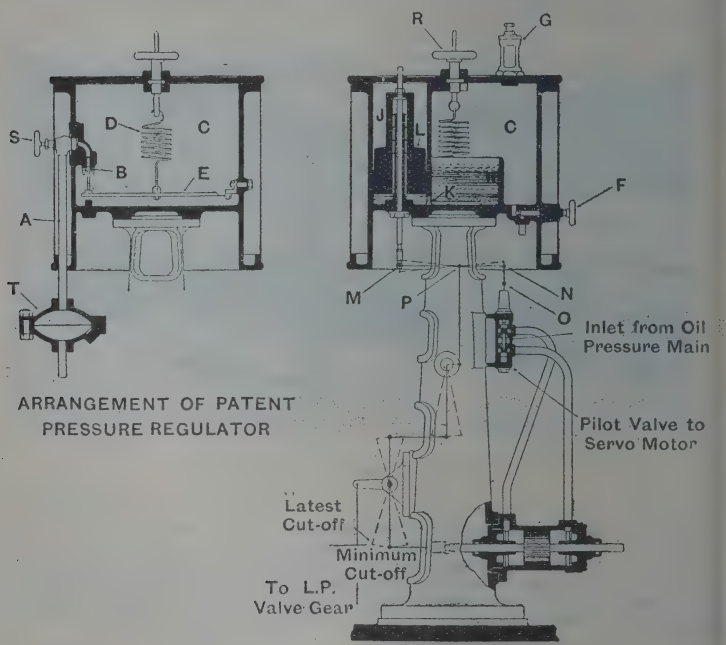

FIG. 21c.—The Galloway Steam Pressure Regulator.

In some combined power and heating schemes conditions arise where the demand for heating steam exceeds that available from the engine at the power at which it is called upon to work at the moment, and it becomes necessary to supplement the supply from the high-pressure main through a reducing valve. The regulator described is able to perform the extra duty of controlling this additional supply. The apparatus is also quite suitable for use independently of a heat-extraction engine for maintaining a constant pressure in a main, or for controlling a reducing valve.

ENGINE DESIGN.

The type of engine is first settled from a consideration of duty, steam consumption, price of fuel, space available, working conditions, water supply, first cost, etc.

Cylinder proportions and speed of revolution are then fixed. Typical British cylinder ratios and mean effective pressures are given in the tables below. On the European Continent the cylinder ratios adopted are usually considerably below the tabular values. That is, a larger high-pressure cylinder is adopted. This makes for economy with superheated steam, but for a two-crank engine tends towards unequal distribution of load on the two cranks which is not altogether desirable. This objection does not apply in the case of tandem engines. These remarks are illustrated by the test results tabulated on page 1767.

TYPICAL MEAN EFFECTIVE PRESSURES AT NORMAL FULL LOAD IN LBS. PER SQ. IN.

Having fixed the cylinder sizes the probable steam pressures on the pistons are put down, and from these the total piston loads are obtained. From these, by allowing suitable stresses and bearing pressures the principal sizes are fixed.

Usual stresses in high-class engines are as follows:—

USUAL ENGINE STRESSES.

Crank and crosshead pins, up to	9,000 lbs. sq. in.	Connecting rod bolts	4,000–6,000 lbs. sq. in.
Crankshaft journals	7,000–9,000 „	Main studs and bolts	5,000 „
Piston rod, net tension at cotter hole	5,000–6,000 „	Lesser „ „	4,000–6,000 „
Piston rod, gross tension (direct plus bending in body)	9,000 „	Connecting rod body, small end	3,000–6,000 „
		Shear on cotters	3,000–5,000 „
		Bending on cotters	up to 7,000 „
		General forgings	4,000–8,000 „

Cast Iron in Tension.

Simple frames, direct pull	700–900 lbs. sq. in.	Flywheel arms (C.F.)	1,500–2,500 lbs. sq. in.
Frames, with some bending	500–800 „	Cylinder barrels, new	1,200–2,000 „
Complex frames, with bending	500–600 „	„ „ usual	1,500 „

It should be noted that in calculating the above frame tensions only the direct pull is included. If bending is calculated separately and added on, very high figures are sometimes reached.

As an example, take the case of a cotton mill engine of 1,500 i.h.p. normal load, the engine to be of the cross-compound condensing type; boiler pressure 160 lbs.

The cylinder ratio we take to be 4 nominal, piston rods being ignored. We aim at equal loading on the two cranks so that of the total drop in pressure from stop valve to condenser one-fifth will take place in the low-pressure (l.p.) cylinder. Allowing 12 lbs. vacuum and losses of 5 lbs. and 8 lbs. at the steam pipe and intermediate receiver respectively, the total effective pressure drop is 159 lbs., of which 32 takes place in the l.p. cyl. and 127 in the h.p. If the engine has a stroke of 5 ft. and runs at 66 r.p.m. (higher speeds are coming into favour), the piston speed is 660 ft. per min., and the area of the l.p. cylinder for a m.e.p. of 30 lbs.

$$= \frac{1,500 \times 33,000}{660 \times 30} = 2,500 \text{ sq. ins.}$$

This is taken as the gross piston area, giving a diameter of 56·5 inches. The actual m.e.p. would therefore be about 31 lbs. The h.p. cylinder should then be 28·25 ins. diam., but odd dimensions are unsatisfactory, and the cylinders will be fixed at 28 and 56 inches, giving a nominal m.e.p. of 30·5 lbs., which is rather below modern practice, which tends rather to higher m.e.p. than given in the table above.

Ignoring the piston rods, the gross load on the l.p. piston is $32 \times 2,500 = 80,000$ lbs. The load on the h.p. piston is the same. Owing to the effect of the rods this value is rather high, but the difference may be ignored, and 5 per cent. added to cover variations in the load distribution, making the total piston load 84,000 lbs. Taking bearing pressures of 1,250 and 850 lbs. per sq. in. on the crosshead pin and crank pin, the projected areas of these become 67·2 and 98·8 sq. ins. respectively. We may thus fix the pin bearings (diam. × length) as 6·75 × 10 and 10 × 10. ins.

HORIZONTAL ENGINE BEARING PRESSURES.

Bearing.	Lbs. per Sq. In.	Bearing.	Lbs. per Sq. In.
Crosshead pins	1,200–1,300	Second motion bearings	100–200
Crank pins	800– 950	Crosshead slides	40– 50
Crankshaft journals (steam load)	100– 150	Intermediate piston rod slides	20– 40
Crankshaft journals (combined loads)	150– 200		

USUAL BEARING PRESSURES FOR VERTICAL HIGH-SPEED ENGINES.

Bearing.	Lbs. per Sq. In.	Bearing.	Lbs. per Sq. In.
Main bearings	200– 300	Crosshead slippers	40–50
Crank pins	400– 550	Eccentric straps	60–70
Crosshead pins	1,000–1,200		

Inertia should be allowed for in special cases.

Journal speeds are rarely taken into account, but there is at present a tendency to do so, especially in Germany. The influence of speed is complex. In many cases it improves the load which can be carried, but it also increases the heat developed per second, and where the pressures are not such as to endanger the oil film, may limit the safe load on the bearing by the tendency towards overheating. For this a rule of the form—

Pressure per sq. in. × journal speed in ft. per sec. = constant,

is used, but the 'constant' varies so widely that its value in the present state of knowledge is limited.

We now turn to the size of the crankshaft neck. The bending 'arm' from centre of crank pin to centre of main crankshaft neck, we estimate at about 26 ins., so that the bending moment is $M = 84{,}000 \times 26 = 2{,}180{,}000$ inch lbs. The twisting moment is

$$T = 84{,}000 \times 30 = 2{,}520{,}000 \text{ inch lbs.}$$

The equivalent bending moment is

$$M_e = \tfrac{1}{2}\left[M + \sqrt{M^2 + T^2}\right] = 2{,}755{,}000.$$

Adopting a stress of 8,000 lbs. per sq. in., the modulus of the neck section is

$$Z = \frac{2{,}755{,}000}{8{,}000} = 344.$$

For a solid neck of diam. d, $Z = 0{\cdot}0982d^3$. Hence $d = 15{\cdot}2$ ins., say 15·5 ins. The length of the neck must be determined to give a suitable bearing pressure from dead weight and steam load.

The piston rod diam. is next fixed, and partly from it and partly directly from the load the proportions of the connecting rod. The piston rod is proportioned so that the stress round the cotter hole at the crosshead is about 5,000 to 5,500 lbs., whilst the total direct tension plus tension due to bending (assuming a tail support to the rod) does not exceed about 9,000 lbs. The net section of the frame will lie between about 100 and 170 sq. ins. according to type, the highest stresses being allowed where there is least bending.

The size of the crosshead slipper is determined as follows:—If the connecting rod is 5 cranks long, centre to centre, divide the total piston load by 5. The result, 16,800 lbs. in this case, is approximately equal to the maximum load on the slide due to piston pressure. To this should be added the dead weight in the case of a horizontal or inclined engine, giving, say, about 18,000 lbs. in all. Taking a pressure of 45 lbs. per square inch (less if the pressure is steady and not highly variable), gives a slipper area of 400 sq. ins.

Testing Crankshaft Alignment.

Place the crankshaft, fig. 22, on its top centre and set either a micrometer gauge or a gauge made of round iron between the crank webs at the bottom. Turn the crankshaft

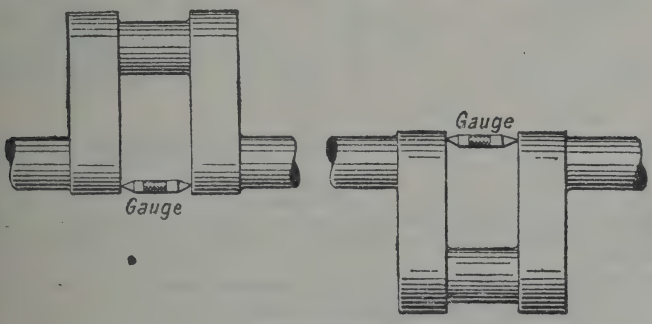

FIG. 22.

around till it is in its bottom position and gauge again. In many cases it will be found that the gauging in the two cases is different, indicating incorrect alignment. Usually, it is the bearing on the driving side that is low. (*A. Bennett, in 'Power.'*)

A simple form of crankshaft alignment indicator, of dial reading type, has been introduced by Messrs. Ruston & Hornsby, Ltd., Lincoln. This instrument is set between the crank webs, and the dial read after turning the shaft into various positions, want of alignment being indicated by differences in the reading.

(See also 'Alignment of Crankshafts and Engine Parts,' p. 1951.)

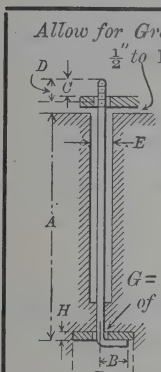
FRAMES.

Bedplates and other frames are almost invariably of strong cast iron. They should be so formed as to reduce bending to a minimum consistent with convenience for the engine attendant and reasonable cost. To secure this they should be as nearly as possible symmetrical on both sides, and also above and below the centre line. This does not mean strict geometrical symmetry, as this is very rarely attainable except as regards the two sides; but it implies an approximately equal distribution of stress. Circular bored and turned joints make for truth in alignment and often for cheapness in manufacture. Ample bearing surface on the foundations must also be allowed.

Foundation Bolt Dimensions.

For bolts 2 ins. or over in diameter, a nut is used under the washer or anchor plate, instead of the bolt being clinched, as indicated by dimension *B*.

STANDARD DIMENSIONS FOR SETTING FOUNDATION BOLTS.



Foundation to rest on Hard Pan, Ledge or Piling.

(*'Machinery,' Mar.* 24, 1921.)

CYLINDERS.

Cylinders should be hard and strong. Apart from questions of strength, for information on which see the table of stresses on page 1791, the following important points should not be overlooked :—

(1) The clearance volume should be as small as reasonably possible.

(2) The clearance surface should be reduced to a minimum.

(3) The exhaust and inlet ports are better separated.

(4) The ports should be short, direct, and not too large. Large ports involve increased clearance surface.

(5) The covers which, however, are closely influenced by the piston details, should be free from recesses and curves.

(6) Where there are jackets the steam should be arranged to have a decided through flow, the more rapid the better.

(7) Proper relief valves and drainage should be provided.

(8) Metal bosses and projections connecting to the frames or atmosphere facilitate heat radiation, and should be kept small.

The clearance surface is specially important. Some particulars of usual practice are given in the table of tests on p. 1766, and in the following :—

TYPICAL CLEARANCE SURFACES.

Cylinder and Valves. (Piston Area × 2 = 100%.)	Surface, Per cent.	Authority.
H.P. slide valve	200	J. Stumpf
L.P. trick valve	180	,,
H.P. piston valve	300	,,
L.P. piston valve	220	,,
Double-beat drop valve	182	,,
Corliss valve	170	,,
Uniflow, double-beat valve	133	,,
H.P. Corliss valve	210–320	Foster
L.P. Corliss valve	180–300	,,
H.P. drop-piston valve	210–300	,,
L.P. drop-piston valve	200–300	,,

The port sizes are based on a steam velocity of 100 to 125 feet per second for inlet ports, and 90 to 120 feet per second for exhaust ports when using saturated steam. With superheated steam these speeds are increased to 130 or even 150 feet per second.

BEARINGS.

With very rare exceptions oil is dragged into a bearing by the relative movement of the two so-called rubbing surfaces by a kind of wiping or dragging action. To prevent loss of lubrication the oil must not be allowed to escape from the bearing except at the proper place. Ordinary crosshead pin bearings work mostly by suction. The slight pulsation of the pin in the bearing draws in oil on alternate strokes. On the return of the pressure the oil has not time to escape.

Oil grooves should be looked upon as local supply reservoirs.

Bearing clearances should not increase so rapidly as the diameter of the journal. They vary according to the class of work.

The use of white metal bearings (see page 2725) is a safety precaution in case of overheating. It also has constructive merits.

Usual bearing pressures are given on page 1792.

For the Michell bearing see page 2408.

Rubber *v.* Metal Bearings.

In many commercial uses metal is now being replaced by rubber.

On a harbour tug rubber bearings showed no wear after ten months. They stand the hard use better than bearings of metal, and speeds as high as 5,000 revolutions per minute have been reported with bearings of this type. One great advantage of rubber bearings is that they are not injured by sand or grit. Such particles imbed themselves in the rubber and work out into the grooves in the bearing, whence they are washed away by the water, the only lubricant necessary, without having scratched or cut any part of the machine. In addition, rubber bearings greatly reduce vibration and noise, and for that reason are being used more and more on yachts, house-boats, and other passenger craft.

The contrast in the wearing qualities of rubber and bronze is shown in the case of a mixing machine. Its arms of bronze lasted six weeks, and gave considerable trouble, but its arms when covered with ½ in. of rubber were working satisfactorily after many months of use. Rubber linings have been known to increase the life of flues carrying gases containing abrasive dust, and also the service of sheet-metal chutes.

Alignment Pins.

'Alignment,' 'steady,' or 'fixing' pins are brought into service in the erection of machinery details for the purpose of ensuring that one particular piece shall be superimposed upon another piece in its precise and correct position, no matter how many times the respective pieces may be separated. The use of such pins is far preferable to fitting bolts to each and every hole; the holes for the bolts should be 'clearance' holes, *i.e.* holes through which the bolts can pass freely.

Fig. 23 shows a pin which has been used frequently in small engines, dynamo-electric machinery, and, notably, in the casings of large steam turbines, with unqualified success.

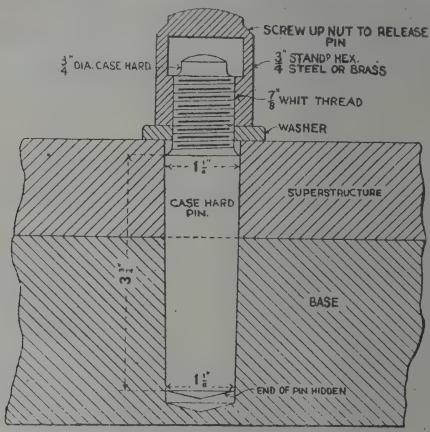

FIG. 23.

It will be observed by those familiar with the use and application of these alignment pins, that a pin such as is shown in the figure is all but imperatively necessary where it is required to fit it to a blind bottom, as represented above. (*'The Electrical Review,'* Sept. 17, 1920.)

FLYWHEELS.

A = Area of turning moment curve per revolution = Work done per revolution in ft. lbs.
a = Excess or deficiency of turning moment curve from resistance curve (usually taken as the mean steady load) = k A.
k = Coefficient of energy fluctuation.
I = Moment of inertia of flywheel in lbs. ft.²
d = Diameter of gyration of wheel in feet.
D = „ rim face „ „
C = Number of complete turning-moment cycles per revolution.
G = Total weight of wheel in lbs.
W = Effective „ „ „ if placed at rim face, diameter D, velocity V.
V = Linear velocity of rim face, ft. per sec.
N = R.P.M.
X = Cyclic irregularity of turning.
Y = Angular deviation from true uniform turning.
F = Frequency of (electric) alternations per second.
p = Number of poles in alternator field magnets.

$$K = \text{Flywheel coefficient} = \frac{\text{Stored energy in flywheel}}{\text{Work done per revolution}} = \frac{WV^2}{2gA}.$$

Then (the suffixes $_1$, $_0$, and $_2$ referring to maximum, mean, and minimum),

$$X = \frac{N_1 - N_2}{N_0} = \frac{V_1 - V_2}{V_0} = \frac{k}{2K} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$K = \frac{k}{2X} = \frac{a}{2AX} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$Y_1 - Y_0 = 28{\cdot}65\,\frac{X}{C} \quad . \quad . \quad . \quad . \quad \text{mechanical degrees} \quad . \quad . \quad . \quad . \quad (3)$$

$$= 14{\cdot}32\,\frac{pX}{C} \quad . \quad . \quad . \quad . \quad \text{electrical degrees} \quad . \quad . \quad . \quad . \quad . \quad (4)$$

$$= \frac{1719\,FX}{NC} \quad . \quad . \quad . \quad \text{electrical degrees} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

The formulæ (3), (4), and (5) are based on sine curves for the turning moment, and are rarely strictly correct as regards the angular deviation $Y_1 - Y_0$, but formulæ (1) and (2) are always correct if the value of a is properly determined.

Considerable uncertainty arises as to the value of a in the case of multi-crank engines.

It is usual to specify that for alternators the angular displacement must not exceed $2\frac{1}{2}$ electrical degrees. In that case, we obtain from equation (4) the relationship

$$\text{coefficient of irregularity } X = \frac{1}{5 \cdot 73} \frac{C}{p} \quad . \quad . \quad . \quad . \quad . \quad (6)$$

In the B.E.A.M.A. standardisation rules for electrical machinery, the rule is given

$$\text{cyclic speed irregularity} = \frac{k}{6p} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where

k = engine impulses per revolution ; p = number of poles.

This formula differs from (6) only in replacing 5·73 by 6, but, as already pointed out, these formulæ depend upon the form assumed for the turning moment curve, and variations are therefore not unlikely and do not indicate any error in principle.

Certain flywheel data are given in the three following tables. It will be understood that these are typical values, and that considerable variations occur in practice.

TYPICAL VALUES OF ENERGY COEFFICIENTS, k.

Engine.	Cranks.	Double or Single Acting.	Cycles per rev. C.	k	Crank Angles.
Steam engines :

Six cylinders	3	0·07	2·7	3·5	4·4	5·3	7·0	8·8

NOTE.—The values of k are based on the assumption of a uniform engine load, and do not apply accurately to engines driving pumps, blowers, or even electric alternators. (*Foster.*)

Example.—Tandem compound engine of 1,200 i.h.p. normal load at 94 r.p.m., driving an alternator of 50 cycles. The deviation must not exceed two electrical degrees on either side of the mean position.

From the tables we see that k is about 0·13, and C=2.
In formula (5) we have

$$C = 2,\ Y_1 - Y_0 = 2,\ F = 50,\ N = 94$$

Hence $$X = 0{\cdot}00437 = \frac{1}{229}.$$

Inserting the value of X in formula (2) we obtain K = 14·9.
The work done per revolution is

$$A = \frac{1{,}200 \times 33{,}000}{94} = 421{,}000 \text{ ft.-lbs.}$$

The stored energy in the flywheel is KA or 6,280,000 ft.-lbs.
If the flywheel is 18 ft. diam., the rim velocity is 88·6 ft. per sec., and the equivalent weight at this diameter is, therefore, 51,500 lbs. The actual flywheel weight should be about 70 per cent. in excess of this, say 87,500 lbs. This makes no allowance for the flywheel effect of the alternator rotor, which is usually considerable and need not be ignored.

For engines driving alternators, the flywheel effect should be such that the displacement $Y_1 - Y_0$ does not exceed 2·5 electrical degrees, nor should X as a rule exceed $\frac{1}{250}$. Where several units have to work in parallel the flywheel effect must also be such as to avoid resonance, i.e. the natural period of oscillation of the rotor about the position of uniform turning must not coincide with the period of any periodic impulses due to the engine. The determination of the oscillation period requires knowledge of the electrical characteristics of the alternators.

Alternator builders commonly state the flywheel quantity of their alternators in terms of GD^2, which is short for weight multiplied by the square of the diameter of gyration. If the units employed are kilogrammes and metres, the corresponding GD^2 in lbs. and feet can be obtained by multiplying by 23·7.

$$\text{Stored energy} = GD^2 \times \left(\frac{\pi N}{60}\right)^2 \times \frac{1}{2g} = \frac{GD^2 \times N^2}{23{,}500}.$$

If G, D are in lbs. and feet, the stored energy is in ft.-lbs. The stored energy at the revolutions of the machine is readily calculated by assuming any convenient diameter of gyration, calculating the corresponding weight and velocity and thence the kinetic energy. The flywheel effect is sometimes stated as T tons (or lbs.) at 1 ft. radius. The GD^2 is then T × 4 in tons (or lbs.) × feet^2. The actual diameter need not be known, which is a convenience of this method of expression. Occasionally the moment of inertia is given, which is equal to GD^2 divided by $4g$, which is 128·8 in ft.-lb. units and 39·24 in kg. metre units. (This gives the moment of inertia in 'engineers' units,' i.e. mass × length^2 ÷ g.)

SPEED OF FLYWHEELS

The rim of a flywheel is subjected to stress on account of centrifugal force, and this stress is independent of the cross-section. For a particular material it depends only on the linear speed of the rim.

For cast-iron wheels the safe rim speed is customarily taken as 6,000 ft. per minute. For a given r.p.m. this fixes the wheel diameter.

Where higher speeds are desired with consequently lighter wheels for the same amount of stored energy, cast steel may be used, or the wheel may be made with discs of steel plate.

A steel plate wheel with wire-wound rim has been run at 15,000 ft. per minute.

Crank Connecting-Rod Mechanism.

If r = crank radius; l = length of connecting rod; n = R.P.M.; θ = crank angle (measured from inner dead centre); x = per cent. stroke of piston (measured from end of stroke remote from crank),

then the following relationships are nearly exact:

$$x = \frac{1 - \cos\theta}{2} + \frac{r}{8l}\left(1 - \cos 2\theta\right);$$

$$\text{piston velocity} = 2\pi nr\left(\sin\theta + \frac{r}{2l}\sin 2\theta\right) = 2\pi r \times k_1;$$

$$\text{piston acceleration} = 4\pi^2 n^2 r\left(\cos\theta + \frac{r}{l}\cos 2\theta\right) = 4\pi^2 n^2 r \times k_2.$$

Table of Crank Angles and Factors for Piston Velocity and Acceleration.

θ = angle of crank for out-stroke.
Angle for in-stroke = 180 − θ, measured from outer dead centre.

Stroke per cent.		$\frac{l}{r}$ = infinity.			$\frac{l}{r} = 5$			$\frac{l}{r} = 4$

94	6	151·6	0·475	−0·88	148·5	0·435	−0·76	147·6	0·425	−0·735
96	4	156·9	0·39	−0·92	154·4	0·355	−0·775	153·5	0·345	−0·745
98	2	163·7	0·28	−0·96	161·9	0·25	−0·79	161·3	0·245	−0·748
99	1	168·5	0·20	−0·98	167·2	0·175	−0·795	166·7	0·175	−0·749
100	0	180·0	0	−1·00	180·0	0	−0·80	180·0	0	−0·75

The positions of piston and crank for zero piston acceleration are as follows:

	$\frac{l}{r} = \infty$	$\frac{l}{r} = 6$	$\frac{l}{r} = 5$	$\frac{l}{r} = 4$	$\frac{l}{r} = 3$	$\frac{l}{r} = 2$
Stroke per cent.	50	46·1	45·4	44·4	43·2	41·7
Crank angle (degrees)	90	80·8	79·1	76·7	73·2	67·7

Crank Effort and Turning Moment.

The crank effort is the force exerted by the connecting rod on the crank pin in the direction of motion of the pin.

The turning moment (at a particular crank) is the crank effort multiplied by the crank radius.

The total turning moment of an engine is the sum of the moments at all the cranks.

To find the crank effort: From the indicator diagram (the assumed probable diagram in the case of design) and the cylinder area, the total force exerted on each side of the piston by the steam is found for any point of the stroke, and hence also the nett steam force on the piston.

To this must be added, with due regard to algebraic sign, the inertia force, *i.e.* the force required to accelerate (or retard) the reciprocating masses. If the engine is vertical, the weight of the moving parts must also be allowed for.

Thus the force P, say, acting at the crosshead in the direction of motion is found.

To find the inertia force at any position of the piston, it is usually sufficient to find the inertia at the ends of the stroke and to find the position at which the inertia is zero, thus fixing three points on the diagram, fig. 24. A fair curve drawn through these points gives the inertia line RRR.

At the inner dead centre, the acceleration $\alpha = 4\pi^2 n^2 r\left(1 + \frac{r}{l}\right)$; at the outer dead centre $\alpha = 4\pi^2 n^2 r\left(1 - \frac{r}{l}\right)$, and $\alpha = 0$ at a position depending on the ratio $\frac{l}{r}$ (see above table).

The inertia force = mass of reciprocating parts $\times \frac{\alpha}{g}$.

Fig. 24 shows the form of a typical diagram of forces. AB is the stroke, A the inner and B the outer end. PPP represents the resultant force of the steam on the piston during the out-stroke and QQQ that during the in-stroke. RRR is the inertia line. Ordinates measured from RRR represent the forces at the crossheads in the direction of motion. (For a vertical engine, the line RRR is lowered by an amount representing the weight of the parts.)

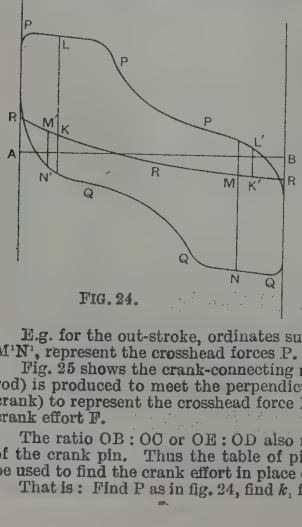

Fig. 24.

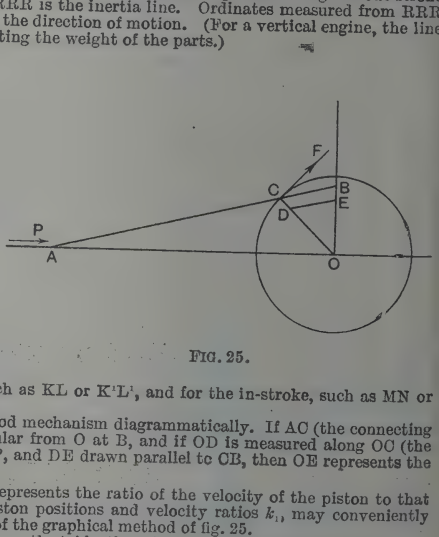

Fig. 25.

E.g. for the out-stroke, ordinates such as KL or K'L', and for the in-stroke, such as MN or M'N', represent the crosshead forces P.

Fig. 25 shows the crank-connecting rod mechanism diagrammatically. If AC (the connecting rod) is produced to meet the perpendicular from O at B, and if OD is measured along OC (the crank) to represent the crosshead force P, and DE drawn parallel to CB, then OE represents the crank effort F.

The ratio OB : OC or OE : OD also represents the ratio of the velocity of the piston to that of the crank pin. Thus the table of piston positions and velocity ratios k_1, may conveniently be used to find the crank effort in place of the graphical method of fig. 25.

That is: Find P as in fig. 24, find k_1 from the table, then the crank effort = force P $\times$ k_1.

Starting Torque of Two-Crank Engines.

Engines which have to start against load, such as locomotive engines, winding engines, etc., have usually two cranks at right angles. They should be large enough to start from any crank position with full steam pressure in the cylinders. The starting torque has minimum values at four points in the revolution occurring just after one crank has passed the position of cut-off. At these points, when the steam stop-valve or throttle-valve is opened, only one of the cylinders receives steam and its crank may be in a very unfavourable position.

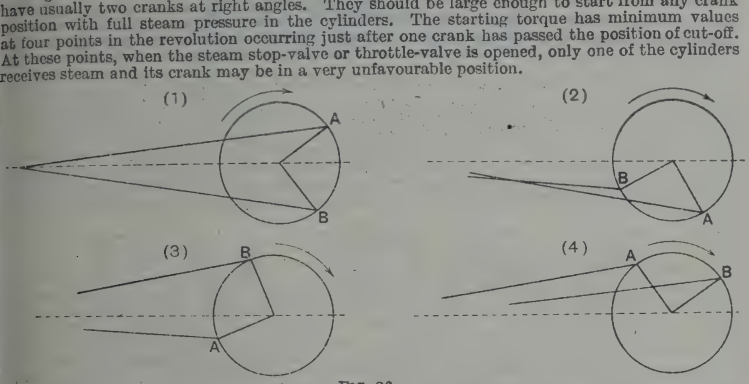

Fig. 26.

The four positions of minimum torque are shown in Fig. 26. In position (1) crank A has just passed the cut-off position on the out-stroke; in (2), B has just passed cut-off on the in-stroke; in (3), A, and in (4), B have just passed cut-off. The worst position is (1).

The ratio of the minimum starting torque to the torque produced by the steam load in one cylinder acting at full crank radius, or as it is often termed 'the equivalent crank ratio,' depends on the point of cut-off. For an engine in which the connecting-rod crank ratio is 5, its values are shown in the following table:

Cut-off per cent.	Position 1.	Position 2.	Position 3.	Position 4
70	0·25	0·39	0·56	0·37
75	0·34	0·475	0·66	0·49
80	0·44	0·56	0·755	0·62
85	0·54	0·645	0·845	0·74
90	0·66	0·74	0·92	0·855
95	0·79	0·84	0·99	0·96

For estimating stresses in the shaft, etc., the maximum torque must also be known.

The combined torque due to two cranks at late cut-off reaches maximum values at four points in the revolution. Two of these points are when the cranks are both above the centre line and at 45°, and when both are below at 45°. The ratio of the torque to that due to one cylinder at full crank radius is then 1·414. Another maximum position is when crank A is at 135° from the inner and B at 45° from the outer dead centre, the ratio being then 1·214. The fourth position is with A at 135° from the outer and B at 45° from the inner dead centre, and this gives the largest ratio of all, namely 1·614.

If the cut-off is sufficiently early, the steam valve of one cylinder will close before the above positions are reached, and the steam pressure in that cylinder will have fallen due to partial expansion: the torque will thus be reduced somewhat as compared with late cut-off.

Annealing Connecting Rod Bolts.

In the annual report of *The British Engine, Boiler & Electrical Insurance Co., Ltd.*, for 1924, attention is drawn to the serious results caused by the defective annealing of the connecting rod bolts of an engine.

The Company state that the heat treating of bolts, shafts, or other parts by rough and ready methods cannot be too strongly condemned.

The malpractices, which take place when 'annealing,' have arisen owing to the prevalence of a vague idea that it is possible to restore metal which has been overstrained in service to its original condition by some form of heat treatment.

A common practice of heating parts to an indefinite temperature and for an indefinite period, and following up by protracting the rate of cooling without having any regard to the quality of the material can only lead to trouble.

The following remarks describe a treatment which is suitable for restoring a machined article such as a connecting rod bolt made of plain carbon steel, to a state of passivity, providing th deformation caused by the overstrain has not been sufficient to set up an incipient internal flaw in this latter contingency any form of heat treatment is only likely to intensify the defect, and th bolt should be scrapped. The recommendation is based on the assumption that the steel wa initially supplied to the user in a suitable condition with regard to heat treatment, and in making it consideration has been given to the uncertainty as to the past history and exact analysis of th bolt :—

The bolt should be heated uniformly in a specially designed muffle furnace to a temperatur in the neighbourhood of 550° C., and at any rate not exceeding 600° C., for a sufficient time t enable it to reach a uniform temperature throughout. In general, with the temperature named the actual rate of cooling adopted is not of great importance as long as it does not exceed tha which takes place in still air ; in certain cases, however, the maximum rate named is to be pre ferred, and is perhaps therefore the most suitable for a general recommendation. Whatever method of cooling be adopted, care must be taken to ensure that cooling is uniform throughou the mass of the steel. Under no consideration should the bolt be cooled on a metal floor o exposed to a draught.

GOVERNORS.

It is the function of the governor to adjust the quantity of steam to the load on the engine The sensitiveness of the governor should depend on the nature of the load, but in all cases th governor should be as free from friction (which also applies to all the valve mechanism operate by the governor) as possible. Friction tends to coarse governing and hunting. On the othe hand, a very sensitive governor, especially if of great power on an engine with insufficient fly wheel, tends to produce hunting, which should be corrected by an oil dashpot on the governo mechanism. In governor design attention must be paid to the levers and connections so a to give a reasonably equal ratio of governor movement to speed variation at all loads.

The plain Watt fly-ball governor is rarely used, being deficient in power. When loade with a central weight (Porter governor) it is satisfactory on typical factory engines, especiall if carried on ball-bearings and knife edges throughout. The centre weight makes it somewha sluggish in following changes of speed, and springs replace the weight in many modern governors The springs need not be vertical.

If the governor is mounted on the crankshaft it may become bulky owing to its slow speed, bu has some merits where eccentrics or valve rods have to be moved directly. Shaft governors owing to their bulk, tend to be sluggish and to lag behind the engine when the speed changes This inertia effect has been utilised in the inertia shaft governor, in which it is the falling behin of the governor weights due to inertia and not their outward movement under centrifugal forc which operates the valve gear.

Relay Governors.

In relay governors the movement of the valve gear is effected by a motor, usually taking th form of a cylinder and piston operated by oil pressure. The movement of the piston is controlle by a small sensitive governor, usually of the centrifugal type. This governor has only to move th oil valve and can be relatively small, whilst the force exerted by the relay piston may be anythin desired. The oil is supplied by a reciprocating or, more usually, a rotary pump. A simpl drum or toothed-gear pump is entirely satisfactory. Any pressure can be obtained, but 5 or 60 lbs. sq. in. is a convenient value. In calculating the pump capacity allow for the maximun reasonable movement of the relay piston, and for 25 to 50 per cent. slip at the pump accordin to the speed, size, and pressure of the pump. These governors are common on large turbines an growing in favour for large oil, gas, and steam engines. Unlike the ordinary centrifugal governo insufficient power shows itself chiefly by slow action and not very much by a large difference i the rising and falling speeds. In short, the relay governor is, under these conditions, slow bu accurate.

Governors are best driven by gears, but chains may be used and even belts or ropes if th last two are in duplicate or triplicate to minimise trouble in case of one belt or rope breaking.

Governors are best arranged to knock off at over speed, but this function may be arrange for by a simple separate governor.

Governors are often termed 'expansion' or 'throttle' governors, but these expression refer to the valve gear rather than the governor. Expansion control is the more economica in most cases, but more difficult to arrange for except in the case of engines having Corliss o drop valves and running at moderate speeds only.

Area of Steam Passages and Valves.

The area is usually calculated from the mean piston speed. Thus if the pipe or valve are is one-tenth the piston area and the piston speed is 600 ft. min. or 10 ft. sec. the steam spee through the pipe or valve is 100 ft. sec.

Usual values for steam and exhaust valves, ports, and pipes :—

Saturated steam	100 ft. per sec.
Superheated steam	125 ,,

For drop-seated valves add about 50 per cent. at high speeds, and up to 100 and 150 per cent. for uniflow engines.

For steam turbines base on actual weight of steam, but assumed saturated, and allow 90 ft. per sec. This is equal to about 120 ft. sec. for steam superheated about 150° Fah. at the turbine. A rough rule is 1000 lbs. of steam per hour at rated load per sq. in. of pipe area.

For the main steam range, unless this is very short, base on actual volume, assumed saturated, flowing at about 90 ft. per sec.; rather less, say 75 to 80 ft. per sec., for reciprocating engines or pipes below 4 ins. in diameter.

PACKINGS.

General Notes.

A packing may operate on two principles. It may, as its name implies, pack the stuffing box as tight as possible, stopping every channel of escape and relying on the quality and lubrication of its materials to prevent undue friction; or it may employ accurately fitting stop-plates and rings adjusted to give minimum friction and thus permitting a very trifling leakage, which if sufficient to be noticeable is sucked away to the intermediate steam pipe or exhaust, as the case may be. All the old and many of the new packings were on the first principle. Some of the new are on the second; and for valve spindles, where friction is most undesirable, the second should always be adopted. In turbines the second is almost universal, the fitting being very slack but not casual, and the leakage considerable.

Hard and fast rules cannot be established as to the composition of the materials which should be used, as these depend on the actual running conditions, but long experience has shown that packing rings of a metallic structure are far superior to the older forms of soft packing; in fact, modern conditions have made the necessity of the change from the one to the other imperative.

The remaining factor in the efficiency of a packing is the design, and it is indisputable that the best results are secured when adjustments to wear and change in pressures are obtained automatically, since the care of machinery is not always entrusted to experienced and skilled workmen.

The United States Metallic Packing.

This packing is made in four distinct forms: 1, block type of packing; 2, cone or locomotive type of packing; 3, duplex type, consisting of combination of the block and cone types; 4, atmospheric-duplex type, specially designed for use on low-pressure condensing cylinders.

The United States Duplex Packing.

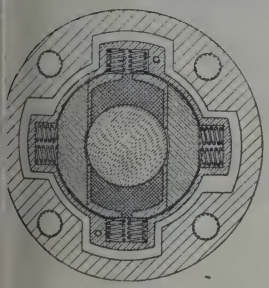

FIG. 27.

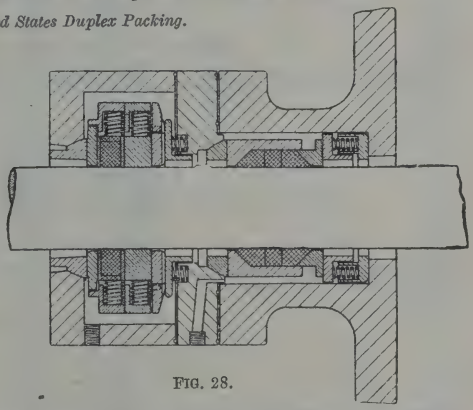

FIG. 28.

Figs. 27, 28, show the duplex type of packing. The block portion consists of eight blocks which are held in strong rings, having pockets or horns holding springs. The packing blocks are put together in sections, four blocks to a section. Each section is, therefore, composed of two working blocks, babbit lined, and two guide blocks. The joints between the blocks in one section are at right angles to those in the other section, thus breaking joint. The blocks are regulated by springs, which merely keep the parts in place when steam is shut off, as when the steam is applied the steam pressure regulates and sets the packing. A ball-joint on one side and follower with springs on the other give the packing free play and keep it steam-tight, without regard to the vibration of the rod. It works equally well whether the rod vibrates or not, and, causing no friction, it does not wear the rod, but gives it a high polish. With efficient lubrication the blocks wear very slowly, many of the packings having given over twenty-four years' service without renewal of the blocks.

The cone portion of the duplex packing consists of three white metal rings placed in a floati cup, the interior of which is partly conical. This cup rests against ball and socket-ring, and t whole is kept in place by a follower with suitable springs, which allow the packing free play in all its movements. The whole is enclosed in a strong case, and bolted to the cylinder head with the usual stud bolts. The packing is steam setting, hence the friction is reduced at least 50 per cent. as compared with non-steam-setting packings. Drain valves are provided for removal of water, core sand, or other accumulations.

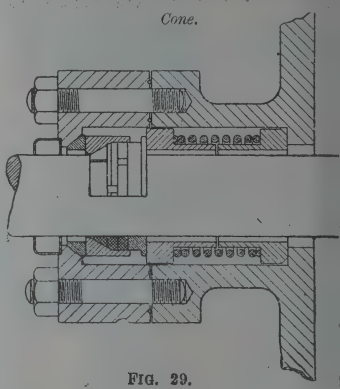

FIG. 29.

The block type of packing is used for pressures under 100 lbs. per square inch. The duplex type is employed for pressures over 100 lbs. Either packing can be arranged for working with steam superheated to 700° F.

Fig. 29 shows the cone or locomotive type of packing, which is practically similar to the cone packing described above. The white metal rings are the only parts which require renewal, and it is no uncommon thing for locomotives to run 80,000 to 100,000 miles without requiring adjustment of packing. All packings can be arranged to pass over enlarged ends.

THE UNITED KINGDOM SELF-ADJUSTING ANTI-FRICTION METALLIC PACKING.

The arrangement of this packing is shown by fig. 30. The only wearing parts are the rin C, D, L, M, which are of special anti-friction metal. These rings are fitted on the rod in segmen

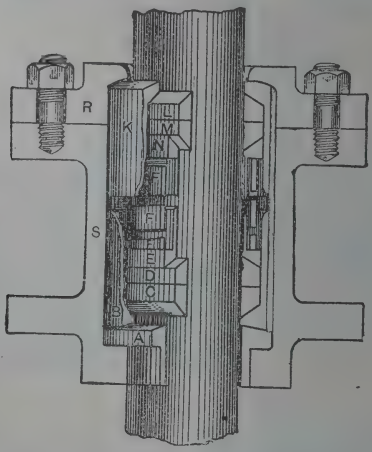

FIG. 30.—A, Neck Bush; B and K, Gunmetal Sleeves; C, D, L and M, Special Anti-Friction Metal Rings; E and N, Gunmetal Spring Rings; F, Steel Coil Spring; R, Gland; S, Stuffing Box.

taking the shape of a truncated cone held together by gunmetal sleeves (B and K) and ke in their place by gunmetal spring rings (E and N), which in their turn are compressed by th steel coil spring (F) placed between them. At the end of the sleeves (B and K) are concentri spherical bearings which allow of free lateral motion where there is any inaccuracy in the runnin of the rod.

The angle on the rings for the purpose of wedging them on the rods to make a steam-tigh joint being more than double that in general use in metallic packings, the friction on the ro

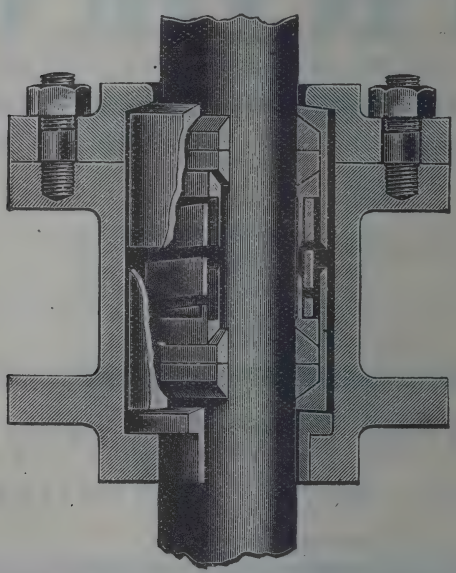
THE UNITED KINGDOM SELF-ADJUSTING ANTI-FRICTION METALLIC PACKING (PATENT)

The Simplest and Most Durable Metallic Packing for all classes of Engines

Perfectly Elastic. **Keeps Rods True.**
Prevents undue wear to Rods.
Admits of Drain Cock in spring space



Small number of parts. **No multiplication of springs.**
Lasts for years without renewal.
Minimum of wear on Rod and least possible amount of friction.
Can be fixed and removed with less trouble than any other.

PACKING SUPPLIED TO HOME, COLONIAL, AND FOREIGN RAILWAYS AND LARGEST ENGINE BUILDERS.

Many Thousands in Use. *All Packings Guaranteed.*
Specially Adapted for Superheated Steam and Refrigerating Machine.

F. 1805

is extremely small, thus reducing the wear on the special metal rings and the rod itself to a minimum.

For swell-ended and large rods a slightly different arrangement of the gunmetal rings is adopted but under no circumstances are screwed parts necessary.

A special feature in the arrangement of the 'United Kingdom' packing is that it cannot be tampered with. It yields freely to all vibrations of the rod which it packs, and also tends to support it, because the concentric spherical bearings at the end of the brass sleeves, which contain the wearing parts, will not allow the packing to drop vertically, although it can angle in any direction, pivoting about the piston head.

It is claimed that the friction is less than one-fourth that with any other existing form of packing, this result being effected by the packing being double, an inner packing throttling the steam in the stuffing-box, so that instead of the outer packing having to withstand the full cylinder pressure, it has only the wire-drawn steam in the stuffing-box between the two packings to contend with.

In addition to the reduced friction, the wearing parts are much larger than is usually the case. It is stated that this packing has for a test been run for six months on an engine doing hard work, without any other lubrication than there is in the steam, and that it was in perfect order at the end of that time, the rods showing no sign of wear.

'BRITIMP' BRAND METALLIC PACKINGS, SINGLE RING TYPE.*

(*British Metallic Packings Co., Ltd., 7 Princes Street, Westminster, S.W.* 1.)

This patent packing consists of three or more rings (fig. 31), each ring forming a complete packing in itself. Each ring is in three segments, which are held together by a garter spring. The joints between consecutive segments overlap in such a way that the combined resistance of the rings to steam leakage is such that perfectly steam-tight glands are ensured. Moreover, the joints are so designed that the parts are reduced to the smallest possible number. Attention is drawn to the fact that there is an entire absence of locating pins which in the course of time are apt to either become loose or be sheared off.

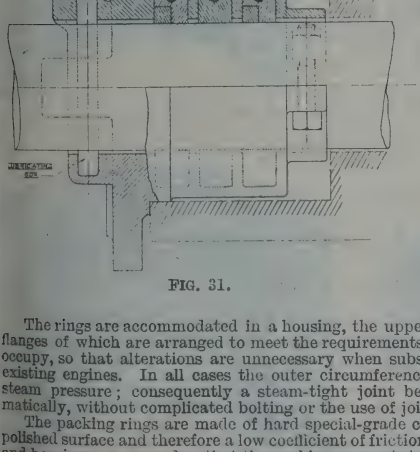

FIG. 31.

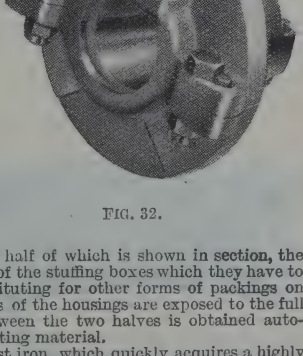

FIG. 32.

The rings are accommodated in a housing, the upper half of which is shown in section, the flanges of which are arranged to meet the requirements of the stuffing boxes which they have to occupy, so that alterations are unnecessary when substituting for other forms of packings on existing engines. In all cases the outer circumferences of the housings are exposed to the full steam pressure; consequently a steam-tight joint between the two halves is obtained automatically, without complicated bolting or the use of jointing material.

The packing rings are made of hard special-grade cast iron, which quickly acquires a highly polished surface and therefore a low coefficient of friction. All contact surfaces between packings and housings are ground so that the packing responds to any lateral movements of the piston rod with a minimum of resistance.

A lubricating box is provided. In cases where there is dust present in the atmosphere this box is provided with a metal scraper ring, which prevents foreign matter from entering the packing.

F. 180

'Lion' Metallic Packing.

(James Walker & Co., Ltd., Lion Works, Woking, Surrey.

Fig. 33 (p. 1806) shows the Block type of this packing. The packing is made in folds and not in layers, the fabric being taken and folded up on itself, so that the steam getting between these folds causes it to expand both to the rod and the box. This was the original type made by Messrs. James Walker & Co. Ltd., and it is still largely used.

Fig. 34 shows a more recent type of packing. This 'Lion' Expanding packing is made on an expanding principle, and in this instance, instead of the pressure acting upon the folds of cloth, there is a V recess in the top of the packing, into which the pressure finds its way and causes an expansion to the rod and the box.

It will be seen that with either of these types of packing, when there is no pressure there is no friction, and when the pressure is on the friction is reduced to the smallest minimum on account of the internal pressure alone being required to ensure tightness, no pressure from an external gland being necessary. Both the above types of packing are used for steam purposes, and the expanding type for hydraulic work.

Fig. 35 shows a set of Block packing in section, and fig. 36, a set of the Expanding type in section.

The Automatic type of 'Lion' packing shown in fig. 37 is used principally for hydraulic work. The recess is made on the face of the packing, an arrangement which, it is claimed, is unlike any other type. The action of the Automatic packing is practically the same as that in a ram leather, and the pressure getting at the back of the lip causes it to swell out to the ram of the accumulator or pump.

Fig. 38 shows a set of packings in section; between each turn of packing there is a recess, and the pressure getting into these recesses is baffled. The Automatic packing will stand a test pressure of over 4,000 lbs. per sq. in.

One very important feature with regard to these packings is that a metallic wearing face is formed by the introduction of white metal studs or pins, in order to form in a stuffing-box the same principle of a white metal bearing that is obtained in an ordinary bearing; that is to say, there is a white metal lateral bearing. The studs are so placed that they touch the rod at all points, thus securing a complete metallic wearing surface which reduces friction, does away with the scoring of the rod, and lengthens the life of the packing.

Beldam's Patent Excelsior Metallic Rings (Duplex Type).

(The Beldam Packing & Rubber Co., Ltd., 16 Gracechurch Street, London, E.C. 3.)

These packing rings are specially adapted for superheat, the highest steam pressures, and for L.P. rods of the reciprocating and turbine combination engines.

This packing has been designed in order that the pressure of steam through the neck bushes of the cylinders shall be gradually counterbalanced and cushioned by the pressure of the receivers.

With this system the rings are maintained in equilibrium, thereby preventing any undue wear, the rod being subjected to a minimum of friction.

All the rings are self-adjusting and interchangeable.

Beldam's Patent 'V' Pilot (Tri-Bar) Packing (for Highest Steam Pressures).

(The Beldam Packing & Rubber Co., Ltd.)

This packing is constructed from a single flexible white metal bar, pure asbestos, and high quality steam-resisting rubber, and is specially designed to stand the highest pressures.

The advantages claimed are as follows:—

(1) It ensures an entirely metallic bearing surface on the rod on the slightest pressure of the gland.

(2) The single bar is so constructed that when formed in the 'V' shape the slots on the face are staggered, thus preventing any possibility of the steam escaping down the rod.

(3) These slots also serve a useful purpose in holding oil, thus ensuring the rod being well lubricated.

(4) Rods will not be scored, but, on the contrary, will be kept in perfect condition.

(5) The packing is very strong and pliable, and easily bent round the smallest rod.

Under steam this packing expands so much that the gland nuts require to be only finger tight, and the gland should enter the stuffing box the depth of one turn of packing to allow for slackening back of gland nuts.

Beldam's 'A' Serpent Packing.

(The Beldam Packing & Rubber Co., Ltd., 16 Gracechurch Street, London, E.C. 3.)

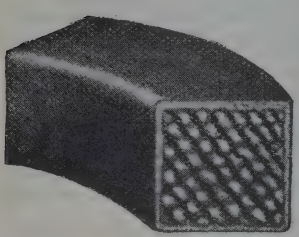

Fig. 39.

This packing, fig. 39, is for superheat and high pressure steam, and is specially recommended for expansion glands and boiler mountings. Owing to its cross-expansion construction, it is claimed to keep a gland steam or water tight with a minimum of friction on the rod.

The packing is built of alternate layers of metal and cloth placed diagonally, thus forming—as can be seen from the illustration—a series of sliding surfaces each of which comes into play on the slightest pressure of the gland.

The main feature of this packing is that the character of the wearing surface never varies, there being no flaking of material, as is the case with rolled cloth packings.

Bell's Patent 'Reefer' Packing

(Bell's United Asbestos Co., Ltd., Southwark Street, London, S.E.1.)

'Reefer,' figs. 40 and 41, is a high-grade semi-metallic packing made in two forms—for steam and hydraulic work. The packing is constructed with a channelled core of anti-friction white metal with side and rear cushions of Bell's Pure Asbestos Cloth (Duck for hydraulic work), proofed with india-rubber and impregnated with best quality plumbago; this form of construction gives a remarkable economy in weight; its design provides for the maximum

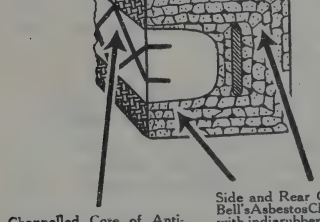

Fig. 40.

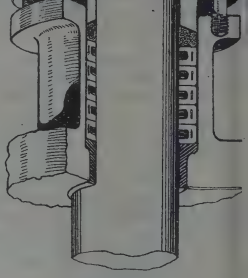

Fig. 41.

surface of anti-friction metal in contact with the piston rod, while using the minimum weight of metal required to give this surface. 'Reefer' is stated to be much lighter than any other packing of its class; it adapts itself to variations in pressure, temperature, and sudden load and keeps the piston rods in first-class condition, giving smooth silent service with the minimum of attention. In several instances 'Reefer' has run without replacement for twelve months while in one case a set of 'Reefer' packing rings ran 12,000 miles on high pressure work and were then in sufficiently good condition for transference to the intermediate pressure, where they gave a further spell of duty. 'Reefer' packings, both steam and hydraulic, are supplied in cylindrical tin boxes, each containing the necessary header material. All sizes from ⅜ in. to 1½ in.

A Long Life Packing

For half a century Bell's United Asbestos Company has taken an inflexible stand on quality, and supplied packings which are truly economical because manufactured from best materials.

Reefer – the Packing

is the only Asbestos and Anti-friction Metal Packing which provides a perfect bearing surface to the rod without a corresponding increase in weight. The Asbestos Cushions expand under heat, automatically keeping the Stuffing Box tight, and do not harden under the action of temperature and pressure, but remain elastic throughout the life of the packing.

'REEFER' is thus unrivalled for wear, and being 20/30 per cent lighter than other forms of semi-metallic Packing, gives a degree of economy with efficiency hitherto unattainable.

THE LASCAR 'V' PACKING (DUPLEX TYPE).

(*Beldam Asbestos Co., Ltd., Hounslow.*)

The bearing surface of this packing, fig. 42, consists of a number of white metal sections presenting an unbroken and continuous antifriction wearing surface to the rod.

The packing is automatic in its action and allows the rods perfect freedom to move in any direction, owing to the expansive and elastic quality of the sleeve, with the result that the gland nuts need only be finger tight. It is very flexible, being easily bent round the smallest rods.

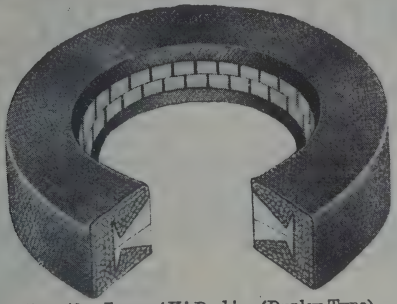

FIG. 42.—Lascar 'V' Packing (Duplex Type).

PISTONS.

THE ROWAN PATENT PISTON.

In the Rowan patent piston (*John Hind & Sons, Ltd.*) absolute steam tightness and absence of friction are obtained by the use of three separate springs, one contained within each packing-ring for outward expansion, and the third lying between the two rings and keeping them in close contact with the piston flanges. These springs are so arranged as to give a *predetermined pressure*

FIG. 43.

FIG. 44.

against the sides of the cylinder. Fig. 43 shows the form of these rings for use with solid piston heads (fig. 44).

'ROWAN' SLOW-ACTION PACKING.

The '*Rowan*' *Slow-Action Packing* (*Hind's Patent*) is a recent development designed to meet the requirements of modern conditions as to high-pressure, high speed, and superheat. In this packing the rings, which are of angle section, have annular grooves turned on the inner side of the flanges, into which is fitted a band of flat steel, which is coiled twice round the inside of the rings, against which it bears. Inside this steel band are two cast-iron spring rings, exerting pressure upon it, and between these is a wave-spring which presses them against the flanges of the piston-ring, thus keeping the latter in steam-tight contact with the flanges of the piston. There are no small or loose parts, the entire packing consisting of six pieces, viz.: Two angle section rings, one steel band, two cast-iron spring rings, and one wave-spring.

The rings are so designed as to give the minimum pressure against the walls of the cylinder consistent with steam-tightness, and, should wear take place, will automatically adjust themselves to the diameter of the cylinder. Should steam get behind the rings, the effect is that the coils of the steel band are pressed together, and the friction so produced absorbs the additional pressure and prevents its being applied to the walls of the cylinder. It is impossible for the steam to get between the steel band and the rings and exert pressure on the rings alone.

Similar action takes place should the rings be subject to circumferential pressure, due to over-running the counterbore or bell-mouth of the cylinder, the pressure of steam being transmitted through the rings to the steel band which is reinforced by the spring rings, when the friction between the coils of the band prevents the rings collapsing.

As these rings will not open and close so freely as the ordinary type of piston rings, they are not suitable for use in worn cylinders, and the makers do not recommend them for such cases but where the bore of the cylinder is in good order they will give satisfaction under the most severe conditions.

The slow-action rings (Class 'S.A.') are not suitable for springing over solid pistons, and pistons which are to be fitted with these rings must be provided with junk-rings.

The Class 'S.A.' rings may, if desired, be arranged to fit into two separate grooves in the piston, instead of one, as illustrated. In this form it is described as Class 'S.A. Divided.'

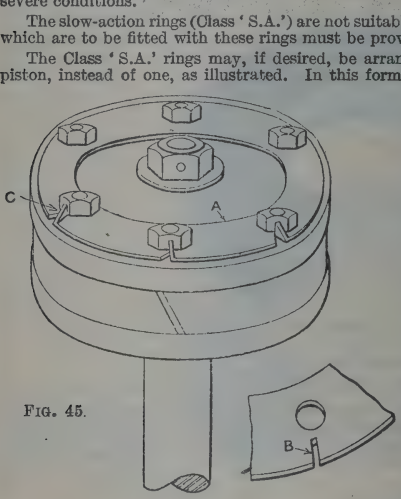

FIG. 45.

It will be obvious from the foregoing that the principle involved renders the 'S.A.' rings suitable, not only for high-pressure pistons, but also for piston valves in which capacity they are stated to give every satisfaction.

NUT-LOCK PLATE.

Fig. 45 shows a lock plate used to hold on the follower plate nuts of a steam engine piston. The circular ring, or plate A, is $\frac{3}{32}$ in. plate steel: the holes are drilled for the studs or bolts and a slot cut on the outside edge to within $\frac{1}{4}$ in. of each hole, as shown at B. The lock plate is put on and the nuts all set up tight; then with a cold chisel the tab is bent up against the flat of the nut side, as shown at C.

(*Machinery.*)

SLIDE VALVE GEAR.

(*Revised by W. C. Popplewell, M.Sc., A.M.Inst.C.E.*)

The movements of an ordinary eccentric driven slide valve are shown by A, fig. 46. S and S_1 are ports leading from the steam chest to the back and front of the piston respectively; E is the port leading to exhaust. The valve itself is shown sliding on the port face. As shown by A, the valve is in mid-position; *ef* is the outside lap, and *gh* the inside lap. As the valve is moved upwards by the eccentric, it reaches a position B where *e* has come opposite *b*, and the steam port S_1 is opening to the steam chest; the amount by which the valve is open at the beginning of the piston stroke is the 'lead.' In position C the steam port is fully open; the valve then returns to D, thus shutting off the supply of steam to the cylinder. This point is 'cut off.' The movement continues until *h* reaches *c*, as at E, when communication is effected between S_1 and E. This point is called 'exhaust.' After opening S_1 fully to exhaust, the valve returns to F, where the exhaust is closed and the point 'compression' reached. This completes the cycle for one end of the valve.

The movements of slide and other eccentric driven valves are analysed by such diagrams as the 'Valve Ellipse' (II, fig. 47), 'Zeuner's Valve Diagram' (fig. 48), and several others designed for the same use. Of these the Valve Ellipse can be made to take account of obliquity of both connecting rod and valve rod, and so yield accurate results. Zeuner's Diagram makes no allowance for obliquity, and in consequence is only approximately accurate, but for purposes of design, where existing data are not available, the Zeuner is the more useful, as it enables the principal dimensions to be approximately fixed. In such a case final adjustments may be completed by using the Valve Ellipse.

Valve Ellipse.

To set this out, begin by drawing the crank circle as at I, fig. 47, and dividing it into a number of equal angles (in this case 8), the crank-pin points being 0, 1, 2, 3, 4, 5, 6, 7. Take the connecting-rod length 1, 1_1, and set it off successively from the crank-pin positions, marking off points on the stroke line 0_1, 1_1, 2_1, 3_1, 4_1. These are positions of the piston corresponding

CROSBY LOCKWOOD & SON'S PUBLICATIONS.

STEAM CONDENSING PLANTS, MODERN PRACTICE IN. A Practical Treatise. By A. R. WRIGHT, A.M.I.C.E., A.M.I.M.E. 320 pages. 185 Illustrations. Crown 4to, cloth. [*Just Published.*] 45*s.* net.

MODERN STEAM BOILERS: THE LANCASHIRE BOILER. A Practical Manual for Owners and Users of Lancashire Boilers. By W. D. WANSBROUGH, Author of 'The A.B.C. of Differential Calculus,' 'The Portable Steam Engine.' 168 pp. with 117 Illustrations. Demy 8vo. 6*s.* net.

LIQUID FUELS FOR INTERNAL COMBUSTION ENGINES. A Manual for Engineers, Designers, Chemists, etc. By H. MOORE, M.Sc.Tech., F.C.S., etc. Second Edition. 206 pp., with numerous Illustrations: Demy 8vo, cloth. 15*s.* net.

STEAM BOILER CONSTRUCTION. A Practical Handbook for Engineers, Boiler Makers, and Steam Users. By W. S. HUTTON. Sixth Edition. Revised and Enlarged. 680 pages, 500 Illustrations. Medium 8vo. 21*s.* net.

THE APPLICATION OF HIGHLY SUPERHEATED STEAM TO LOCOMOTIVES. Being a Reprint from a series of Articles appearing in *The Engineer*. By ROBERT GARBE, Privy Councillor, Prussian State Railways. Edited by LESLIE S. ROBERTSON, M.Inst.C.E., etc. Medium 8vo. 9*s.* net.

THE PRACTICAL ENGINEER'S HANDBOOK. A Treatise on Modern Engines and Boilers, Marine, Locomotive, and Stationary. By W. S. HUTTON. Seventh Edition. Revised and Enlarged. Medium 8vo. 576 pages, 430 Illustrations. 21*s.* net.

TABLES, MEMORANDA, AND CALCULATED RESULTS FOR MECHANICS, ENGINEERS, ARCHITECTS, BUILDERS, SURVEYORS, etc. Selected and arranged by FRANCIS SMITH. Seventh Edition, revised, including ELECTRICAL TABLES AND FORMULÆ. 280 pages, waistcoat-pocket size. *New edition in preparation.*

THE MARINE STEAM TURBINE. A Practical Illustrated Description of the Parsons and Curtis Marine Geared-down Steam Turbines, &c. As presently Constructed, Fitted, and Run (including Turbo-Generators). A Manual of Marine Steam Turbine Practice intended for the use of Naval and Mercantile Marine Engineer Officers, &c. By J. W. M. SOTHERN. Sixth Edition. Rewritten up to date and greatly Enlarged. 950 pages, Illustrated by over 750 Diagrams, Photographs, and Detail Drawings. Medium 8vo, cloth. 40*s.* net.

MECHANICAL HANDLING AND STORING OF MATERIAL. A Treatise on the Handling and Storing of Material such as Coal, Ore, Timber, etc., by Automatic or Semi-Automatic Machinery, together with the Various Accessories used in the Manipulation of such Plant, and dealing fully with the Handling, Storing, and Warehousing of Grain and Coal. By G. F. ZIMMER, A.M.Inst.C.E. 820 pp., royal 8vo, cloth with over 1,000 Illustrations (including Folding Plates) specially prepared for the Work £3 3*s.* net.

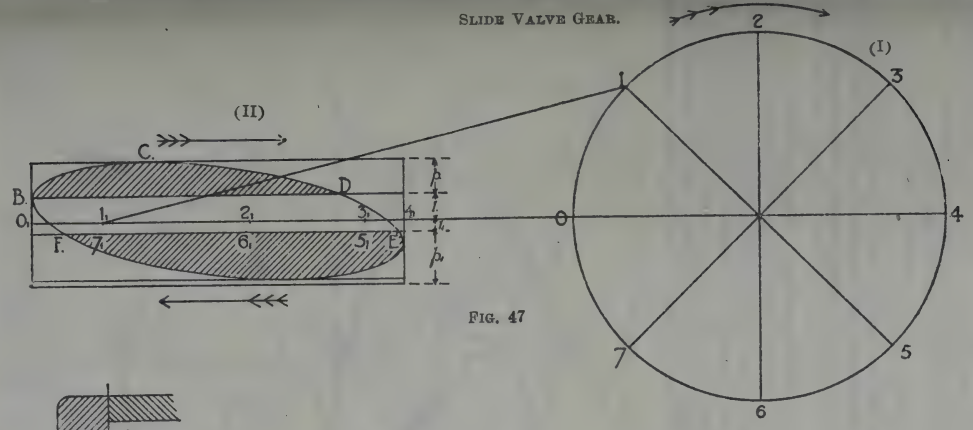

FIG. 47

FIG. 48

FIG. 46.

to 0, 1, 2, 3, 4, of the crank-pin, and are seen at II. A similar construction is followed out for the eccentric circle at III (fig. 48). This is turned through a right angle as compared with I, and the 'angle of advance' is marked $\theta°$. The distances of the valve from its mid-position, corresponding to the successive positions of the piston, are shown below the eccentric circle. These are set up as ordinates from the horizontal points on II, and a smooth curve drawn through the points so found. Thus from $1_{,}$ on the line of piston travel at II is plotted an ordinate which represents the distance of the valve from its central position when the piston is at $1_{,}$; this is the distance from ZZ to the line marked 1 at III. Next draw a horizontal line at distance l above $0_{,}$, $4_{,}$, in II, this is the 'lap' line; also a second line at a distance p beyond the lap line, which is the 'port opening.' Similarly below $0_{,}$, $4_{,}$, are two further lines at $l_{,}$, 'inside lap,' and $p_{,}$, 'exhaust opening.' The points where the ellipse cuts these lines represent the chief incidents in the cycle. They are B (admission), where the valve is just opening to steam; C (full port); D (cut-off); E (release); F (compression).

In the case of the back plate of a gear of the Meyer type, separate ellipses must be drawn for the edge of the plate, and the points where these cut the main ellipse noted.

Zeuner Diagram.

A few of the principal cases are given in what follows. The results are not strictly accurate, because they are vitiated by the angularity of the eccentric rod. But with reasonable proportions a design will be sufficiently near what the diagram shows. Fuller information may be found in Zeuner's treatise, or in the small book of Cowling Welch, who reduced Zeuner's methods to practice.

Reversing gears which do not employ two eccentrics usually derive motion from some point on the connecting rod. Such are the Joy gear and others, for all of which special advantages are claimed under certain conditions, though as valve movements it is doubtful if any give better results than plain link gears. The newer motions often involve considerable sliding movement of a block in an inclined link, this link being pivoted so as to reverse its inclination, whereby the valve, driven by the block which slides up and down in the inclined link, has its movement reversed or varied according to the degree of inclination either way of the link. Such valve movements are best studied by the aid of models, with variable dimensions; made from flat bars of cedar or baywood.

Simple Slide Valve.

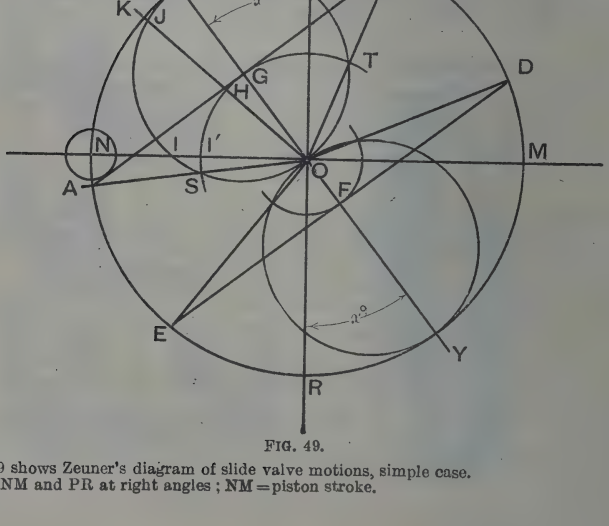

FIG. 49.

Fig. 49 shows Zeuner's diagram of slide valve motions, simple case.
Draw NM and PR at right angles; NM = piston stroke.

OP = OR = valve travel each side of centre point; OA = crank when steam is admitted; OB = crank at cut-off.

Bisect AB. Join OX, OY perpendicular to AB.

$x° + 90°$ = angular advance of eccentric; SGT = outside lap circle: cuts 'valve' circle at ST; OS = position of valve from centre when admitting steam; OT = position of valve from centre when cutting off steam; OF = inside lap; OD = crank when exhaust commences; OE = crank when exhaust closes.

The intercena of any radius from O, cut off by valve circles, shows distance of valve from its midstroke for that crank angle. Thus when crank is at OK valve has moved a distance OJ from its centre and steam port is open a width HJ.

DY = YE. AX = BX. Lead = small circle N = 2 II'.

Double Back-Plate Cut-off.

Figs. 50 and 51 show Zeuner's expansion valve diagram, Meyer valve.

Draw AB, XY at right angles, OD at angular advance $\phi°$ = half travel of main valve; OR = crank at admission: ON = lap circle. Draw OP slightly in advance of latest opening of main valve as shown by point *t*. This gives a minimum cover *ts*. Join PD, and draw OE parallel to it and DE parallel to OP. Then OE = half travel and position of the cut-off eccentric which will

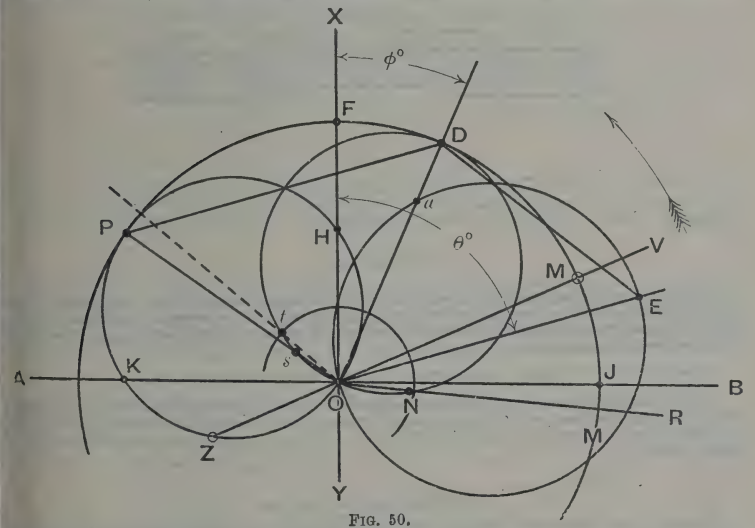

Fig. 50.

cut off steam when the crank, OR, reaches the position OP. It need not cut off later than this, for then the main valve has already acted.

The radius O*a* or any other vector of the cut-off valve circle shows the movement of the cut-off valve from its middle position, OE being the half throw of the cut-off eccentric, and $\theta°$ its angular advance. Any radius vector of the auxiliary circle OP will show the relative displacements of the main and cut-off valves from each other. At the crank position OP the cut-off plates are drawn close together. Draw the large circle APDM through P. Then for any position OV of desired cut-off the length of the cut-off valve must be increased by separating the two cut-off plates of the right and left screw to the amount MZ. To cut off at OX of the crank would demand the movement FH, while to cut off at the dead point OB the movement of the plates would be JK. The length over the steam ports in the back of the main valve will be equal to the sum of the length of the cut-off plates plus twice OP. The edges of the cut-off plates when fully extended have a maximum distance from the main valve centre of JK (or MZ if OM is the earliest desired cut-off). But at no moment must the inside edges of the cut-off plates uncover the inside edges of the ports in the main valve. These ports have a width *a*. At the latest cut-off, viz. at OP, the cut-off plates will be drawn together so that x = nil.

To find movement of cut-off plates from centre for any point of cut-off, as with crank at OV, the plates must be screwed out a distance x = MZ. If cut-off is at OF position of crank, then x = FH.

Taking the position of earliest cut off at OV, to find the proportions L and l of valves which will be a maximum :—

Calling FE = y = L − l − x for earliest cut-off, the maximum relative movement of the valve centres by the eccentrics is OP. Since at the position OV the valve centres are the opposite way removed from cut-off by the amount OZ and that OP is the maximum relative movement, we have L − l = OP when x=nil and x must be OP+OZ = MZ for earliest cut-off. When the crank reaches OP the cut-off valve is moved out already a distance x = MZ and it is moved a further distance OP by the eccentric, so that the outer edge of the cut-off plate is a distance OP+OP+OZ from the middle of the main valve. And when so far the inner edge of the cut-off plate must not overrun the inner edge of the back port a. Therefore L−a=2OP+OZ ∴ L=OP+OP+OZ+a and L−l=OP ∴ l=OP+OZ+a. Since the main valve has cut-off at the position Ot there is safety lap of ts on the main port below even, if the inner edge of the cut-off plate then reaches the port a.

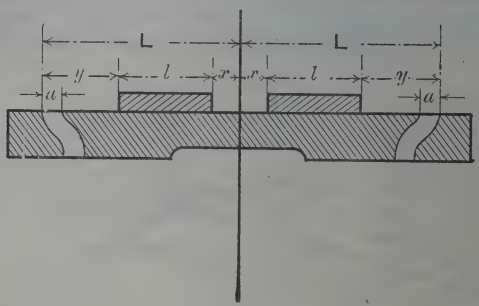

FIG. 51.

In the figure the main valve travels $4\frac{1}{4}$ ins. and the cut-off valve $5\frac{1}{8}$ ins. The cut-off plates are each moved out by screws at earliest cut-off x=$3\frac{1}{2}$ ins., and by eccentric movement $2\frac{1}{8}$ ins. relative to main valve, or a total of $5\frac{5}{8}$ ins. The main valve has a length L=$5\frac{5}{8}$ +a and the cut-off plate (or L−OP=l) a length of $3\frac{1}{4}$ ins. + a.

If a=1 in. then L=$6\frac{5}{8}$ ins. ; l=$4\frac{1}{4}$; x=$2\frac{1}{8}$ ins. maximum plus $3\frac{1}{4}$ screw-out.

If early cut-off is desired in the general working of the engine with quick action the auxiliary circle OP should be near to 90° from the cut-off position of the crank. Thus at the position OD the two valves are moving at high relative speed. It is usual to give the greater travel to the cut-off valve.

LOCOMOTIVE LINK MOTIONS.

These may be investigated also by the Zeuner method. A link motion is simply built up with two eccentrics, either of which may be made to bear fully and directly on the valve spindle and cause an engine to run forwards or backwards. This is accomplished by connecting the two eccentric rods by a link in which the end of the valve spindle is carried. At the extreme end position the spindle is wholly driven by one eccentric, while at intermediate positions the two eccentrics combine to give a gradually shorter movement to the valve.

There are three general link gears. 'Stephenson's,' in which the link is raised or lowered to give the desired position of the spindle block or link block ; and the link is concave to the axle and has a radius equal to the length of the eccentric rods.

'Gooch's,' with link convex to the axle and not movable up and down ; movement of the block being effected by a radius rod and the link having this radius of curvature.

'Allen's,' in which the link is straight and both link and radius rod are raised and lowered in opposite directions.

All three forms are made with open or crossed rods, the former giving greater lead of the valve near the middle position of the link block, and the latter giving less lead towards the middle position. In Gooch's motion the lead is of course always constant.

STEPHENSON LINK MOTION

Open Rod Design.

In fig. 52, AE=link. BD=link block in forward and backward gear. OJ=virtual single eccentrics to give requisite travel to B or D in full gear. Join OB, cutting valve circle on OJ at K. Join JM through K. Then the arc struck from c through JMJ will contain the ends of all the eccentric radii or valve circle diameters for all positions of the slider B or D. Dividing this arc in the same ratio as B divides the link AE will give the ends of the valve circles for each point of the link. And the real eccentrics will have the position and half travel OF, OF just as the ends of the link lie beyond B and D. If the link end-pin comes opposite the extreme

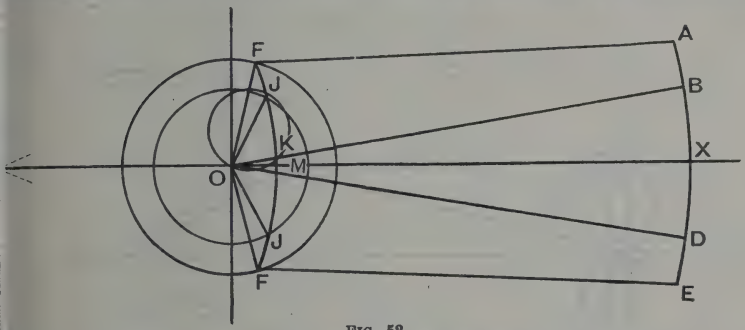

FIG. 52.

positions BD of the block then OJ become the real eccentrics in position and in half throw, i.e. XB : XA : : MJ : MF. Rods are said to be *open* when they are as FA, FE when the eccentric arms point towards the link. With open rods the valve lead increases with the expansion.

Crossed Rod Design.

In fig. 53, AE=link. BD=link block in full forward or backward gear. OJ=virtual single eccentric that would give requisite valve travel in full gear. Join OD, cutting upper valve circle on OJ at L. Join JN through L. N is on the line OX. Then the arc struck from O through JNJ contains the ends of all the valve circles for every position of the slide block, the arc JNJ being divided for each diameter in the same ratio as the slide block divides the link AE.

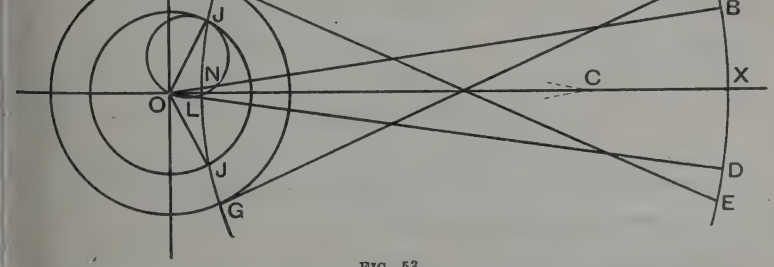

FIG. 53.

Thus OG, OG become the actual eccentric arms, and NJ : NG : : XB : XA. Rods are said to be *crossed* when they are as GA, GE, the eccentric arms pointing towards the link. With crossed rods the lead of the valve decreases with increased expansion. Specially note that OD cutting the valve circle at L is employed in this construction, whereas OB is the line used in the open-rod diagram.

Gooch's Link Motion.

In this motion, fig. 54, the 'curve' of valve circle centres is a straight line aa distant from O an amount $f = \frac{r}{2}\left(\sin\delta^\circ + \frac{c}{l}\cos\delta^\circ\right)$ for the open rod design, and $\frac{r}{2}\left(\sin\delta^\circ - \frac{c}{l}\cos\delta^\circ\right)$ for the crossed rod design, where

r = eccentricity of eccentric or OE;

m is the point from which the link is hung and is a fixed point;

the versed sine of the link arc is $\frac{c^2}{2l_1}$;

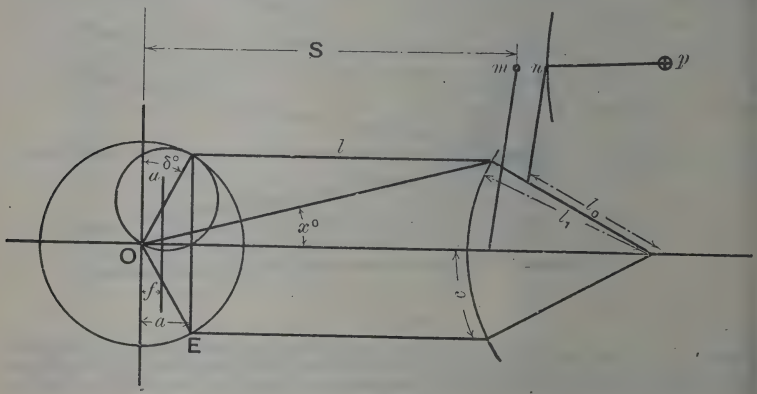

Fig. 54

m is distant from O a length $S = -\frac{c^2}{2l_1}$;

n is the point from which the radius rod is hung;

$On = l + l_1 - l_0 - \frac{c^2(l+l_1)}{2ll_1}$.

The point n should move in a parabola whose parameter $= 2l_1$ or a circular arc of radius l_1.

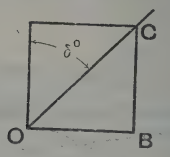

Fig. 55.

The co-ordinates of any point on the curve of centres are as per fig. 55, where

for open rods, $OB = \frac{r}{2}\left(\sin\delta^\circ + \frac{c}{l}\cos\delta^\circ\right)$;

for crossed rods, $OB = \frac{r}{2}\left(\sin\delta^\circ - \frac{c}{l}\cos\delta^\circ\right)$.

$BC = \frac{r\,u}{2c}\left(\cos\delta^\circ \pm \frac{c}{l}\cos\delta^\circ\right)$, according as the rods are open for $-$ or crossed for $+$ signs, where c = half length of the link and u = the variable position distance of the slider block from the middle of the link.

The lead is constant at all grades of expansion. The link is so hung that its middle point moves to and fro horizontally by the combined effect of the arc of swing and the cant due to slope of the link, the suspension link being pinned at the centre of the chord of the link.

The radius rod l_1 is so hung that its to-and-fro motion produces a minimum of sliding of the link block in the link. The extreme positions of n being known the actual arc in which it moves is arranged in practice with a shorter arm np than theory demands, the best compromise possible being accepted which can be arranged under the conditions. The Gooch gear, for any given distance between axle and cylinder, has very short rods compared with the Stephenson gear. Also the angle $\delta°$ in fig. 55 is equal to the angle $x°$ as found in fig. 49, p. 1812, for the simple slide valve, plus the angle $\delta°$ in fig. 54, p. 1816.

ALLEN'S STRAIGHT LINK MOTION.

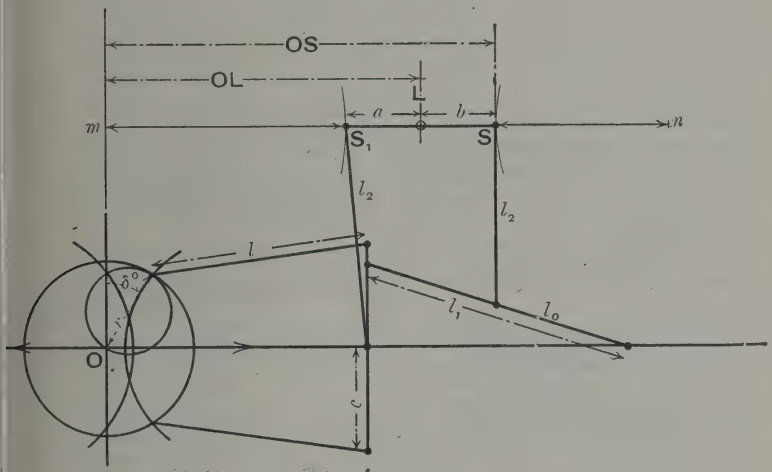

FIG. 56

$$\frac{b}{a} = \frac{l_o}{l}\left(1 + \sqrt{1 + \frac{l}{l_1}}\right); \; n = 1 + \left(\frac{l_1}{l_o}\,\frac{b}{a}\right).$$

Curve of centres is a parabola whose vertex is distant from $O = \frac{r}{2}\left(\sin\delta + \frac{c}{l}\cos\delta\right)$ for open rods, and $\frac{r}{2}\left(\sin\delta - \frac{c}{l}\cos\delta\right)$ for crossed rods, and is concave towards O for open rods, and convex for crossed rods. Parameter for both open and cross rods $= \frac{nlr}{2c\cos\delta}\cos\delta \mp \left(\frac{c(n-1)}{nl}\sin\delta\right)^2$ for which a circular arc may be substituted of one half the parameter.

S and S_1 should move in parabolas of $2l_1$ and $2l$, or in arcs of l_1 and l radius.

As arranged in practice $a + b = (l_1 - l_o) +$ a little extra l_2 as long as possible.

$$Os_1 = \left(l - \frac{c^2}{2l}\right); \; OL = l + a - \frac{c^2}{2}; \; ms_1 = l; \; ns = l_1; \; Os = l + l_1 - l_o - \frac{c^2(l + l_1)}{2ll_1}.$$

Lead increases with expansion with open rods and decreases with crossed rods.

WALSCHAERT GEAR.

(See page 689.)

STEAM TURBINES.*

FLOW OF STEAM—NOZZLES—BLADE EFFICIENCY—LOSSES—PACKINGS—ROTORS—MATERIALS—TEST DATA—TURBINE TYPES—REDUCTION GEARS.

(Contributed by H. L. Guy, Wh. Exh., A.M.Inst.C.E., A.M.I.Mech.E.)

In this section the following symbols have been used in the indicated significance, except where otherwise stated :—

c = absolute velocity in ft. per sec.
g = constant of gravitation = 32·2 ft. per sec.^{2}
H.λ. = heat drop in B.Th.U.
N = speed in r.p.m.
P = pressure in lbs. per sq. ft.
p = pressure in lbs. per sq. in.
t = temperature °F.
T = absolute temperature °F = (460 + t).
U = peripheral velocity in ft. per sec.
v = specific volume in cubic ft. per lb.
W = weight of steam in lbs. per sec.
w = relative velocity in ft. per sec.
λ = ratio of the specific heats of a gas.
ω = angular velocity in radians per sec.
J = Joule's Equivalent = 778 ft. lbs. per B.Th.U.

FLOW OF STEAM.

When steam flows through a simple orifice from a chamber (denoted by suffix 1) into a space (denoted by suffix 2) the velocity with which discharge takes place is always dependent on the steam conditions existing before the orifice, and sometimes dependent upon those existing on the discharge side.

If the pressure, P_1, in the chamber is maintained constant, while that beyond the orifice is gradually reduced from an initial value equal to P_1, the velocity and quantity of discharge gradually increase and depend on the pressure drop over the orifice, until a critical value is reached corresponding to a definite value of the ratio $\frac{P_2}{P_1}$.

Dr. Zeuner† has shown theoretically, and the result is borne out by experiment, that the critical drop is reached when

$$\frac{P_2}{P_1} = \left(\frac{2}{\lambda+1}\right)^{\frac{\lambda}{\lambda-1}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

For saturated steam $\lambda = 1{\cdot}135$, and $\frac{P_2}{P_1} = 0{\cdot}577$.

For superheated steam $\lambda = 1{\cdot}3$, and $\frac{P_2}{P_1} = 0{\cdot}546$.

* See also Marine Steam Turbines, Section XXXVI, p. 2363.
† *Technical Thermodynamics*, Dr. Zeuner.

After this *Critical Pressure Drop* has been reached, the quantity and velocity of discharg remain constant for smaller values of P_2, the discharge being accompanied by strong acousti vibrations.

Dr. de Laval was able to obtain—and used in his turbine—much higher velocities than th critical velocity, by adding a conically divergent nozzle to the orifice. In this way the vibration are eliminated, and although the velocity of exit from the nozzle may be considerably greate than the critical velocity, the velocity at the minimum section or throat of the nozzle and th weight of steam discharged remain unchanged from the values which would exist in a simpl orifice.

From this it will be apparent that there is a discontinuity in the phenomena accompanyin discharge of steam through an orifice or nozzle, and that the equations existing between th various terms entering into the formulæ of steam flow must be considered in two groups.

(a) When the Pressure Drop is less than the Critical Drop.

i.e., when $P_2 > 0{\cdot}577\ P_1$, for saturated steam ; $P_2 > 0{\cdot}546\ P_1$, for superheated steam.

The theoretical velocity c_1 with which discharge takes place, can be calculated from the formul due to Wantzel and St. Venant,

$$c_1 = \sqrt{2g \frac{\lambda}{\lambda - 1} (P_1 v_1 - P_2 v_2)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The actual velocity of discharge c_2 is less than c_1, on account of the friction and eddy losses in the orifice, and is given by

$$c_2 = \phi\, c_1,$$

$$\text{where } \phi = \text{velocity coefficient} = \frac{\text{Actual velocity of discharge}}{\text{Theoretical velocity of discharge}}.$$

The value of ϕ for various cases is given in Table II., page 1824.

The weight of steam discharged per second is given by the relation

$$W = k\, S \frac{c_2}{v_2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where,

v_2 = specific volume of the steam in the lower state, in cubic ft. per lb.
S = the sectional area in sq. ft. of the smallest section or throat of the orifice.
k = coefficient of discharge (see Table II.).

The expansion takes place with very great rapidity and for purposes of calculation it may be assumed to be adiabatic without serious error. The validity of this assumption has been questioned, but Dr. A. Loschge* has proved its approximate correctness by obtaining equal discharge through duplicate nozzles made of metal and of porcelain, and it need only be added that formulæ deduced from this basis agree very closely with experimental results.

For adiabatic expansion—

$$P_1 V_1^{\lambda} = P_2 V_2^{\lambda} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

from which, by combination with (2) and (3), we get

$$W = k S \sqrt{2g \frac{\lambda}{\lambda - 1} \frac{P_1}{v_1} \left[\left(\frac{P_2}{P_1}\right)^{\frac{2}{\lambda}} - \left(\frac{P_2}{P_1}\right)^{\frac{\lambda+1}{\lambda}} \right]} \quad . \quad . \quad . \quad . \quad (5)$$

Alternative Method.

The following method of dealing with such problems, due to Dr. Zeuner, is often more simply manipulated than that already given, especially when used in conjunction with the Mollier or other entropy diagram.

If

H_1 = total heat of 1 lb. of the steam in the higher condition in B.Th.U. ;
H_2 = total heat of 1 lb. of steam in the lower condition in B.Th.U. ;
h_a = the heat drop available for adiabatic expansion = $H_1 - H_2$.

* *Engineering*, October 17, 1913.

Then

$$c_1 = \sqrt{2g \cdot J \cdot h_a} \quad . \quad . \quad . \quad (6), \quad \text{and } c_2 = \phi \cdot c_1.$$

W can be calculated as before from (3); h_a can either be measured directly off a Mollier diagram or calculated from steam tables in the following manner:—

If $t°$ = degrees of superheat; L_1 = latent heat corresponding to P_1; T_1 = absolute temperature corresponding to P_1; h_1 = sensible heat corresponding to P_1; X_1 = dryness fraction of the steam in the higher state; T_2 = absolute temperature corresponding to P_2; h_2 = sensible heat corresponding to P_2; X_2 = dryness fraction of the steam in lower state; ϕ_1 = entropy of the liquid in the higher state; ϕ_2 = entropy of the liquid in the lower state;

then

$$X_2 = \frac{T_2}{L_2}\left[\frac{X_1 L_1}{T_1} + C_p \log_e\left(\frac{T_1 + t}{T_1}\right) + \phi_1 - \phi_2\right],$$

and

$$h_a = X_1 L_1 + C_p \cdot t \cdot + h_1 - X_2 L_2 - h_2.$$

In these formulæ the mean value of the specific heat of superheated steam at constant pressure C_p for the range of the superheat should be taken.

Nozzles which are designed for a smaller pressure drop than the critical are wholly convergent and must be sized according to the methods given in this section.

Simple orifices, the nozzles of Rateau or Zoelly turbines, and both the rotating and stationary blades of Parsons turbines, fall into this class.

(b) When the Pressure Drop is Greater than the Critical Drop.

i.e., when $P_2 < 0{\cdot}577P_1$, for saturated steam; $P_2 < 0{\cdot}546P_1$, for superheated steam.

In this case let the suffix m denote the conditions in the minimum section or 'throat' of the nozzle.

Then whatever the total pressure difference over the nozzle, that from P_1 to the throat pressure is always equal to the critical value, and the nozzle must be convergent to the throat.

By combining (1) with (2) and (4), the velocity in the throat is obtained.

$$= \sqrt{g\lambda \cdot P_1 V_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

if $\phi = 1{\cdot}0$.

(7) is identical with the expression for the velocity of sound in the conditions present in the throat, so that the velocity in the throat, or the critical velocity, is equal to sound velocity.

By substituting from (1) and (4) in (5)—

$$W = k S_m \sqrt{2g \frac{\lambda}{\lambda + 1}\left(\frac{P_1}{V_1}\right)\left(\frac{2}{\lambda + 1}\right)^{\frac{2}{\lambda - 1}}} \quad . \quad . \quad . \quad . \quad . \quad (8)$$

from which the discharge per second can be obtained, S_m being the area at the throat in square feet.

The nozzle from the throat to the mouth must be divergent, the area at the mouth being calculated from the relation

$$S_2 = S_m \cdot \frac{V_2}{V_m} \cdot \frac{c_m}{c_2} = S \left[\left(\frac{2}{\lambda + 1}\right)^{\frac{1}{\lambda + 1}} \left(\frac{P_1}{P_2}\right)^{\frac{1}{\lambda}} \sqrt{\frac{\frac{\lambda - 1}{\lambda + 1}}{1 - \left(\frac{P_2}{P_1}\right)^{\frac{\lambda - 1}{\lambda}}}}\right] \quad . \quad . \quad (9)$$

Expressions involving λ are strictly applicable only when the expansion takes place wholly in either the superheated or the saturated region, the corresponding value of λ being introduced.

The following expressions will be found to give approximately the same results as (9).

For Superheated Steam.

If $P_1 = (1{\cdot}732 \text{ to } 20)\ P_2$ $\quad S_2 = S_m\left(0{\cdot}7175 + 0{\cdot}163\ \frac{P_1}{P_2}\right)$

$P_1 = (20 \text{ to } 100)\ P_2$ $\quad S_2 = S_m\left(1{\cdot}5 + 0{\cdot}125\ \frac{P_1}{P_2}\right)$

For Saturated Steam.

If $P_1 = (1{\cdot}832 \text{ to } 25)\ P_2$ $\quad S_2 = S_m\left(0{\cdot}777 + 0{\cdot}1216\ \frac{P_1}{P_2}\right)$

$P_1 = (25 \text{ to } 100)\ P_2$ $\quad S_2 = S_m\left(1{\cdot}875 + 0{\cdot}0812\ \frac{P_1}{P_2}\right)$

Introducing the numerical value of λ (1·135 for saturated steam and 1·3 for superheated steam), and with $g = 32{\cdot}2$, formula (7) becomes—

For Saturated Steam. $\quad c_m = 70{\cdot}2\ \phi\ \sqrt{p_1 v_1}$

For Superheated Steam. $\quad c_m = 72{\cdot}38\ \phi\ \sqrt{p_1 v_1}$

In the same way formula (8) would produce two expressions for the discharge depending on the condition of the steam as regards superheat. Researches by Loschge* and Bendemann have however shown that the numerical coefficient of the formula for nozzles having a convergent entrance is the same both for saturated and superheated steam, and that this value is 2 per cent. higher than is obtained by inserting $\lambda = 1{\cdot}135$.

This is in accordance with the previously known fact that for saturated steam the discharge from such a nozzle exceeds the theoretical amount.

Just prior to the publication of these researches Mr. H. M. Martin* propounded the ingenious theory that with steam initially saturated an unstable condition exists in the throat, cooling taking place below the saturation temperature without condensation. The decrease in specific volume which results from this 'Under-Cooling' would account for the measured excess in discharge over that calculated on the assumption of adiabatic expansion.

Prof. Stodola has suggested that this under-cooled steam obeys the same law of expansion as superheated steam, so that the experimental fact that the discharge both for saturated and superheated steam is given by one formula is rational and in line with theory.

The formula for discharge deduced from Loschege's experiments is :—

$$W = 44{\cdot}11\ k\ S_m \sqrt{\frac{p_1}{v}}$$

Table I., giving the critical velocity and the discharge per square inch of throat area, has been calculated on the assumption that $b = 1{\cdot}0$ and $k = 1{\cdot}0$; the necessary correction for other values will be obvious.

The following simple formulæ, the first due to Napier and the second to Rankine, are often useful when an error of a few per cent. is admissible.

For Dry Saturated Steam.

$$P_1 > \frac{5}{3}P_2,\ W = \frac{s \cdot p_1}{70}; \qquad P_1 < \frac{5}{3}P_2,\ W = 0{\cdot}029\ s\ \sqrt{p_2(p_1 - p_2)},$$

where s = area of orifice in square inches.

Design of Nozzles.

The values of ϕ and k as determined by experiment are given in Table II. for orifices and nozzles of various kinds.

The coefficient of discharge k depends amongst other things upon the friction loss, the coefficient of contraction, and usually for a pressure drop below the critical, upon the ratio $\frac{P_2}{P_1}$.

Professor Rateau found that for nozzle C the value of k was slightly greater than unity when P_2 is less than $0{\cdot}5P_1$.

* *Engineering*, October 17, 1913.

In reference to nozzles G and H, which are of the types used in impulse turbines, it should be mentioned that although the value $k = 1{\cdot}0$ has been inserted in Table II., Dr. Christlein found that the actual discharge exceeds the theoretical by a few per cent. This effect had already been observed by Mr. Rosenhain for nozzles of form F having well-rounded entrances, and he concluded from his experiments that a loss in efficiency results, and was, therefore, led to recommend that the entrance should be only slightly rounded.

These facts are confirmed by Dr. A. Loschge's researches and explained by Mr. H. M. Martin's theory, which is referred to in the preceding paragraph.

The value of ϕ for nozzle G cannot be very satisfactorily determined from Dr. Christlein's experiments; for a given value of ϵ_1, ϕ appears to increase with the pressure and to decrease with the superheat before the nozzle.

Unfortunately, the results of Mr. Rosenhain's experiments, like those of Messrs. Siberly and Kemble, are vitiated by the fact that the wetness of the steam during the experiments was not measured.

Nozzles of type B are useful for approximate measurements of the amount of steam flowing through a pipe line. It is only necessary to put a thick plate having a cylindrical hole in it between two of the pipe flanges. If the pressure is observed before the plate (P_1) and also in the cylindrical hole (P_2) by means of a hole drilled from the rim through the centre thickness of the plate, the flow can be calculated from formula (5).

Of course, the hole in the plate should be of such a diameter that the ratio $\frac{P_2}{P_1}$ is not less than 0·6.

Several steam meters operate on this principle.

The nozzles of turbines are usually of rectangular cross-section, and the steam in passing through them turns through an angle of about 70°, as indicated in figs. G and H, p. 1825. It is important to bear this in mind when employing data relating to ϕ and k deduced from straight nozzles of circular cross-section—the type usually favoured by experimentalists.

For a given ratio of expansion the length of the nozzle depends on the angle of divergence. If this angle is too great the steam does not completely fill the cone, which results in considerable loss. If the angle is too small the length of the nozzles becomes very great, and many experiments indicate that the friction loss depends on the length. An angle of divergence of 10° is very common.

The experiments of Mr. Rosenhain, and more recently of Messrs. Siberly and Kemble, show that there is no appreciable difference in efficiency for angles varying from 9° to 20°.

If the ratio $\frac{S_2}{S_m}$ is less than that theoretically required, expansion is completed beyond the nozzle. Rateau's experiments demonstrate that when this *under-expansion* is small, little loss results. On the other hand, if $\frac{S_2}{S_m}$ is greater than that theoretically required, the steam is expanded in the nozzle below the condition into which it discharges. Such *over-expansion* results in steam shock with great loss of efficiency.

When the divergent nozzles of a turbine are correctly designed for the normal load, over expansion takes place at overloads, and under-expansion at partial loads, with nozzle cut-out governing.

The entrance of divergent nozzles should be smoothly rounded off, with a radius about equal to the throat diameter; larger radii are unnecessary and should be avoided.

Since the efficiency of a nozzle depends upon the smoothness of the surfaces with which the steam is in contact, the material of which it is constructed should be capable of withstanding erosion and oxidisation—nickel steel or a bronze highly polished is usually employed for the divergent nozzles of De Laval and Curtis turbines where high steam velocities are encountered, while cast in mild steel plates have given quite satisfactory results with the large nozzle areas and moderate velocities used in the convergent nozzles of Rateau and Zoelly turbines.

The state of knowledge on the efficiency of steam nozzles has been recently advanced by the researches carried out for the Nozzle Research Committee of the Institution of Mechanical Engineers by Professor Stoney and Mr. Telford Petrie.

The apparatus used is of the impact plate type, largely designed by Mr. H. M. Martin. The first two reports dealt with tests taken on 1-in. wide reaction blading having a nominal outlet angle of 20°, and on impulse nozzles having an outlet angle of 20° with guide blades 0·04 in thick.

FIG. 1.

The mean velocity coefficient (ϕ) values for the impulse nozzles obtained on those tests are shown on p. 1827, for nozzles with throats of various proportions. The corresponding curves for the reaction blading are shown by the dotted curve.

The notable feature of these tests is that they were carried out as large-scale experiments on commercial blades and nozzles.

The character of the curves, particularly for the impulse nozzles showing a rising value at low velocity, is particularly notable, as the region was not previously explored in published researches.

The third report of the Nozzle Research Committee of the Institution of Mechanical Engineers contains the results obtained with thick plate impulse nozzles summarised in diagram, fig. 1.

It will be observed that although the efficiency of the thick plate nozzles is materially lower than that of thin plate nozzles, the efficiency of the former can be improved to that of the latter by suitably chamfering the outlet.

In this report the experimental results on the efflux angle of the discharged steam suggest that its value is equal to $\sin^{-1}\frac{o}{p}$, and not to the geometrical angle (see fig. 2, and table C).

Experiments were also carried out on straight nozzles well radiused at the inlet and having long parallel throats equal to about three diameters in length.

The efficiency of this nozzle was very high, giving a velocity coefficient θ of about 0·98 for 500 ft./sec., 0·97 for 300 ft./sec., and 0·98 for 1,700 ft./sec.

The experiments also lead to the conclusion that the efficiency of a nozzle is decreased as the superheat is increased.

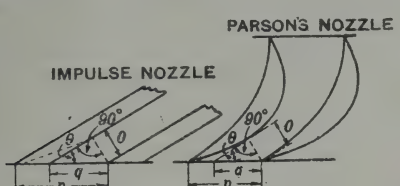

FIG. 2.—Efflux Angles.

Turbine Efficiency.

The 'Overall Efficiency' of a turbine is obtained by comparing the work actually done per lb. of steam, with that which would be performed by an ideal engine working on the Rankine cycle and having the same initial and final steam conditions as the turbine.

The figures in the above table have been taken from the useful and compact 'Heat Drop Tables' published by the British Electrical and Allied Manufacturers' Association.

This latter amount of work is equal to the mechanical value of the change in total heat contents (h_a B.Th.U.) which takes place during adiabatic expansion from the steam conditions before the governor valve, to those obtaining in the turbine exhaust.

h_a is referred to as the 'adiabatic heat drop' or the 'available heat drop,' and its value for the steam conditions usual in practice is given in Table IIIA, p. 1830.

TABLE IIIB.—ADIABATIC HEAT DROP IN B.TH.U. DRY SATURATED STEAM.

If

d = steam consumption in lbs. per S.H.P. hour; N_T = overall efficiency of the turbine,

then

$$N_T = \frac{2,545}{d.\,h_a} \times 100 \text{ in per cent.}$$

If

d_1 = steam consumption in lbs. per K.W. hour; N_G = generator efficiency in per cent.,

then

$$N_T = \frac{3,414}{N_{G1}.d_1.h_a} \times 100 \text{ in per cent.}$$

The total steam consumption of the turbine is given by

$$W = \frac{d\ (\text{S.H.P.})}{3,600} \text{ lbs. per sec., or, } W = \frac{d_1\ (\text{K.W.})}{3,600} \text{ lbs. per sec.}$$

While the efficiency calculated with h_a as already defined is the true index of the performance of a turbine when running, it is sometimes the practice—and it is one which has a special value to turbine designers—to calculate the efficiency by taking the heat drop h'_a as that available between the conditions existing after the governor valve, that is, before the nozzles, and the exhaust of the turbine.

This is equivalent to eliminating the consideration of the pressure drop through the governor valve, which is rightly regarded as not being an inherent loss to any given turbine.

Suppose, for example, that two turbines are sold as 1,000 k.w. units to operate with certain steam conditions, and that one is actually capable of developing a load of 1,100 k.w., while the second can only pull a load of 950 k.w.

If these two turbines are tested on a load of 1,000 k.w., the latter will show the better steam consumption, because with the former the steam will be throttled at the governor to the greater extent. Of course, the first machine is in every way the better from the customer's point of view, provided the excess of power is not too great to be carried by the generator.

The steam consumption which can be used for estimating purposes when using steam at 200 lbs. per square inch, 200° F., and exhausting into a vacuum of 28 ins., is shown by fig. 3 for 1,500

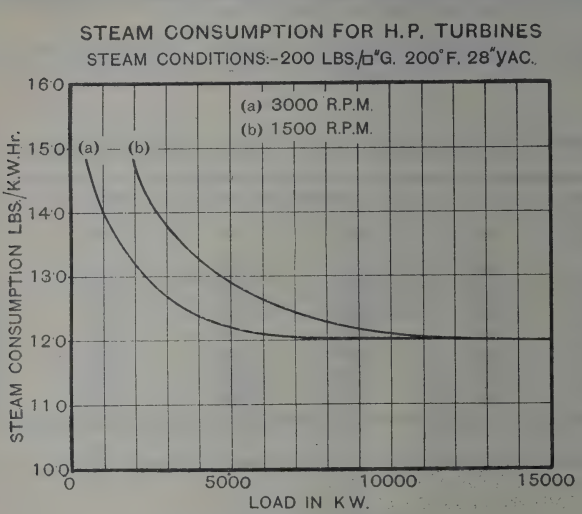

FIG. 3.

and 3,000 r.p.m. The former speed is the highest which can be used for 25-cycle generators, while the latter can be used for either 25 or 50 cycles. These curves illustrate the effect of speed

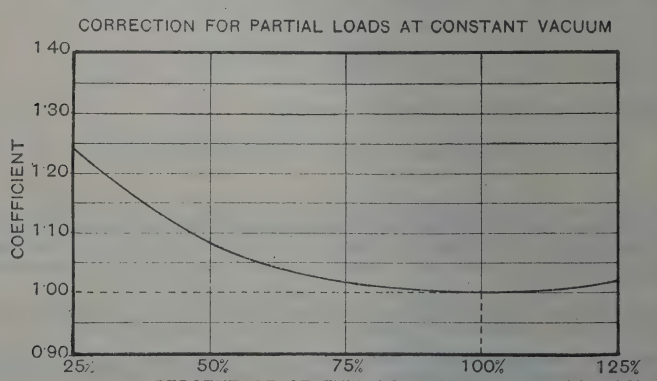

FIG. 4.

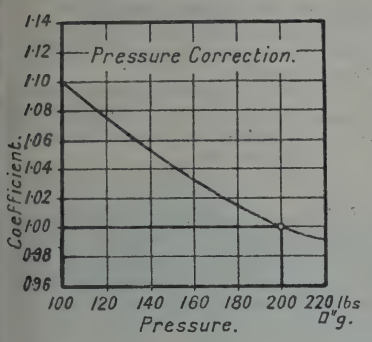
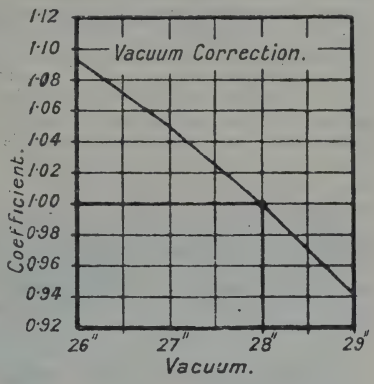
on efficiency. Fig. 4 enables the consumption at fractional loads to be estimated when th consumption at full load is known.

The steam consumption which can be obtained for other steam conditions can be approxi mately obtained by means of the correction curves shown in fig. 5.

STEAM CONSUMPTION CORRECTIONS FOR TURBINES DESIGNED FOR VARIOUS CONDITIONS.





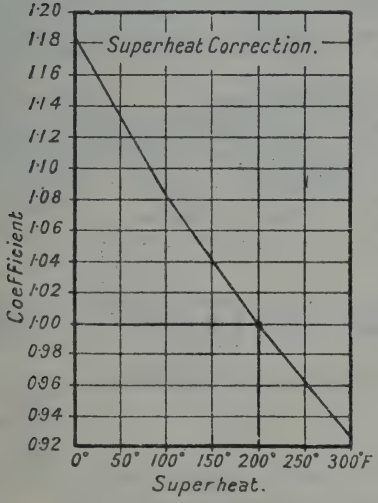


FIG. 5.

STANDARD STEAM CONDITIONS:

200 lbs. per sq. in. g.

200° F.

28 in. Vac.

For other steam conditions, multiply the consumptions obtained from fig. 3 (page 1832) by the coefficients obtained from the curves.

IMPULSE TURBINES.

A pure impulse turbine is one in which the available heat energy of the steam is completely converted into kinetic energy in stationary nozzles.

The steam jet thus produced performs mechanical work by impinging on a rotating row of blades or successive rows of rotating and guide-blades placed immediately before the nozzles.

An impulse turbine in which the whole pressure drop available is utilised in a single set of nozzles is said to consist of one *pressure stage*. If the pressure drop is subdivided between two, three, or more successive sets of nozzles, it consists of two, three, or more pressure stages.

When the kinetic energy of the steam jet is utilised in one row of rotating blades, the turbine is said to have one *velocity stage* per pressure stage. If, after the first row of rotating blades, a guide blade is placed to reverse the direction of steam so as to impinge on a second row of rotating blades, the turbine is said to have two ' velocity stages,' and so on.

Since a minimum nozzle height will be fixed by practical considerations (not less than $\frac{1}{4}$ in. even in the smallest turbines), the arc over which the nozzles will extend depends upon the total nozzle mouth area required. In the high-pressure stages this may be less than the mean circumference of the blades. Such a turbine is said to be working with partial admission, and the arc over which the nozzles extend is termed the ' arc of admission.'

This arrangement lends itself especially well to conveniently and efficiently dealing with overloads, it being only necessary to increase the ' arc of admission ' by admitting steam to additional sets of nozzles.

In the same way it is possible to divide the total number of nozzles into blocks controlled by separate cutout valves. Thus one block of nozzles can be designed to give all loads from 0 to $\frac{1}{2}$ full load, while these together with a second block give $\frac{1}{2}$ to $\frac{3}{4}$ and so on.

By this means the loss of pressure through throttling at the governor valve is reduced to a minimum, and substantial economies can be effected on partial loads. The nozzle cutout valves may be operated automatically or by hand. Nozzle cutout governing is not possible with reaction turbines.

(a) Single Pressure Stage Turbine with a Single Velocity Stage.

The nozzles of all impulse turbines can be designed by the methods already indicated, while the work done and the efficiency can be obtained by drawing the triangles of velocity a_1 and a' (see fig. 6). All velocities are in feet per second.

Let

W = total weight of steam through nozzles in lbs. per sec.; c_1 = absolute velocity leaving nozzles; U = peripheral velocity at mean diameter of blades; w_1 = relative velocity at entry

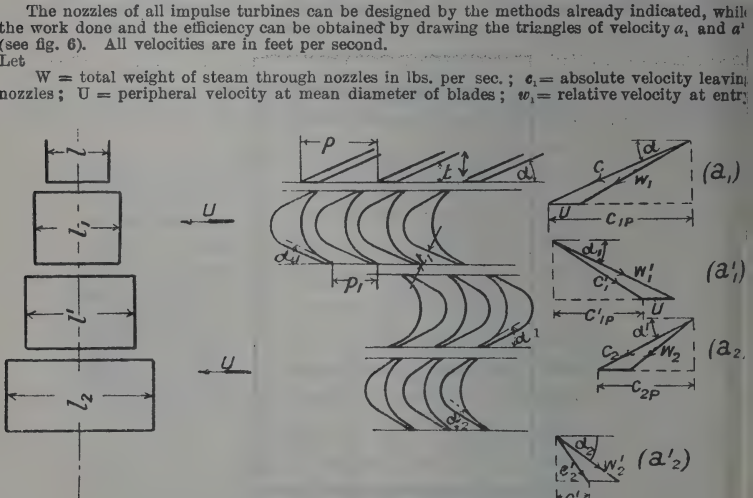

FIG. 6.

to moving blades; w_1' = relative velocity at exit from moving blades; c_1 = absolute velocity leaving the moving blade; c_{1p} $c_1'_p$ = the peripheral components of c_1 and c_1', respectively.

Then

$$w_1' = \psi w_1,$$

where $(1 - \psi_1')$ is the loss of velocity due to friction in the blade (see fig. 10, page 1838)' ψ is called the *velocity coefficient* for the blades.

ESTABLISHED 1852.

The total work done, or
The indicated work $= \frac{W\,U}{g}(c_{1P} + c_{1P}')$ ft. lbs. per sec.

The blading efficiency $\eta_B = \frac{\text{(total work in ft. lbs. per sec.)}}{W.\,J.\,g.\,h_a}$

If

l = the required nozzle height; l_1 = the required blade height;

then

$$l_1 = l \cdot \frac{c_1}{w_2} \cdot \frac{l}{l_1} \cdot \frac{p_1}{p}$$

The de Laval turbine, which is of this type, is made in sizes from 5 to 500 h.p., running at 30,000 r.p.m. in the smallest size, and 10,000 r.p.m. in the largest outputs.

The peripheral speeds are as high as 1,300 ft. per second, and the steam velocity at exit from the nozzles as high as 4,000 ft. per second.

It can be shown that the efficiency varies with $\frac{U}{C_o}$ where C_o is the velocity theoretically obtained if $\phi = 1{\cdot}0$.

For a maximum efficiency, $\frac{U}{C_o}$ should be about equal to 0·5 (see fig. 8, page 1837, which gives the results obtained experimentally by Dr. O. Lasche).

(b) Single Pressure Stage. Two Velocity Stages.

In this case the work done in the first row of blades is obtained in exactly the same way as in case (*a*).

The guide-blade returns the steam jet towards the direction of U, the steam leaving it with an absolute velocity $c_2 = \psi_2 c_1'$.

The relative velocity of exit from the second rotating blade is $w_2' = \psi_2' w_2$, knowing which, the velocity triangles $a_2 . a_2'$ can be drawn. In a_1 and a_1' the same symbols are employed as in a_1 and a_1', a suffix 2 denoting the guide-blade, while a dash denotes the second moving blade.

The total work per second is now

$$= \frac{W\,.\,U}{g}\left\{(c_{1P} + c_1') + (c_2 + c_2')\right\} \text{ ft. lbs. per sec.}$$

WORK DONE IN 1ST AND 2ND ROWS OF VELOCITY WHEELS. 3,000 R.P.M.

Initial conditions :—200 lbs. per sq. in. g., 200° F. supf.; steam pressure in casing = 34 lbs. per sq. in. g.; temperature in casing = 410° F.

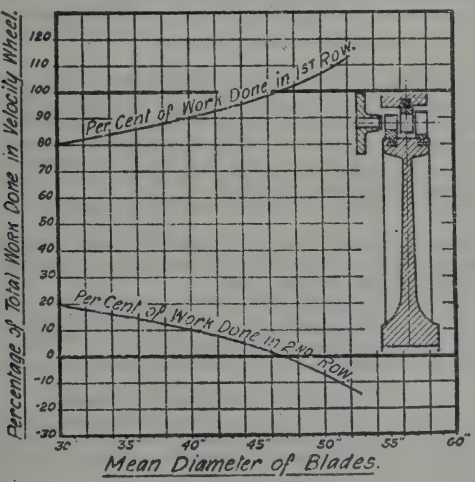

FIG. 7.

and

$$\eta_B = \frac{\text{(Total work in ft. lbs. per sec.)}}{W \cdot J \cdot g \cdot h_a}$$

The height of the guide-blade $l^1 = l \cdot \frac{c_1}{c_2} \cdot \frac{t}{t^1} \cdot \frac{p^1}{p}$

The height of the second rotating blade $l_2 = l \cdot \frac{c_1}{w_2^1} \cdot \frac{t}{t_2} \cdot \frac{p_2}{p}$

As the mean peripheral velocity of the blades increases the proportion of the work done in the first row increases. This effect is illustrated in fig. 7, from which it will be seen that for the condition stated the second row does no positive work if the mean diameter of the blades exceeds 47½ ins.; it can therefore be dropped with advantage. For this reason two-row wheels are rarely used in modern high-speed machines.

(c) Single Pressure Stage. More than two Velocity Stages.

The solution of this case can be obtained from (*b*) in exactly the same way as (*b*) was obtained from (*a*).

Single-wheel Curtis stages belong to classes (*b*) and (*c*) and are very much employed for small high-speed turbines, where efficiency is not the first consideration.

The peripheral speeds for Curtis wheels are as high as 600 ft. per second, and the steam velocity 2,500 ft. per second.

For a maximum efficiency $\frac{U}{C}$ should be about 0·23 for two rows of moving blades, and 0·18 for three rows (see fig. 8, page 1837).

(d) Multi-Pressure Stage Turbine with Single Velocity Stages.

In order that reasonable efficiencies may be reached with practicable peripheral speeds, it becomes necessary to limit the heat drop utilised in each set of nozzles to some value considerably less than the total available between the conditions before the turbine stop valve and those present in the exhaust.

Up to a certain point, which is rarely reached in the conditions of actual design, the efficiency of each stage increases with the value of the ratio $\frac{U}{C_o}$ (see fig. 8, page 1837).

When the value of $\frac{U}{C_o}$ is known, which corresponds to the desired turbine efficiency, the value of C_o and hence of h_a the heat drop to be utilised per stage can be calculated, since U will be fixed by mechanical considerations.

Then for an equal distribution of energy over the pressure stages,

If H_a = the total heat drop available for the whole turbine,

$$\text{The required number of stages } n = e \cdot \frac{H_a}{h_a}$$

where e is the '*reheat factor*' which depends on the amount of friction and eddy losses, the number of stages, the stage efficiency, etc., and varies between 1·03 and 1·07.

It is usually the practice to give the first stage a larger heat drop than the remainder, thus reducing the total number of wheels required, and having the considerable advantage of reducing the maximum temperature and pressure to which the turbine casing is subjected.

Having apportioned the heat drops, the steam conditions at each stage can be found—most conveniently by the Mollier diagram—and each stage can be designed as indicated under case (*a*).

The Rateau and Zoelly turbines are of this type.

In practice U varies from 350–600 ft. and the steam velocities from 800–1,600 ft. per second.

(e) Multi-Pressure Stage Turbines with Multiple Velocity Stages.

In precisely the same way as has been explained under (*d*), two- or three-row velocity wheels may be employed in the individual pressure stages.

The heat drop which can be advantageously used per pressure stage is then greater than in the case where a single row of blades is used, and thus the required number of pressure stages is reduced, but the efficiency is somewhat decreased, as may be deduced from fig. 8, page 1837.

The general design of each stage is similar to that of case (*b*).

The Curtis turbine is of this type.

(f) Combination Impulse Turbines.

It has become a common practice to construct pressure-compounded impulse turbines of type (*d*) with a Curtis wheel having two rows of blades in the first stage. By this means a large heat drop can be employed in the first stage with reasonable efficiency and with the consequent advantages already mentioned.

The Curtis-Rateau and Curtis-Zoelly turbines are of this type.

Diagram showing the best efficiencies obtained in Dr. O. Lasche's experiments on Impulse Wheels. The efficiencies have been corrected for disc friction.

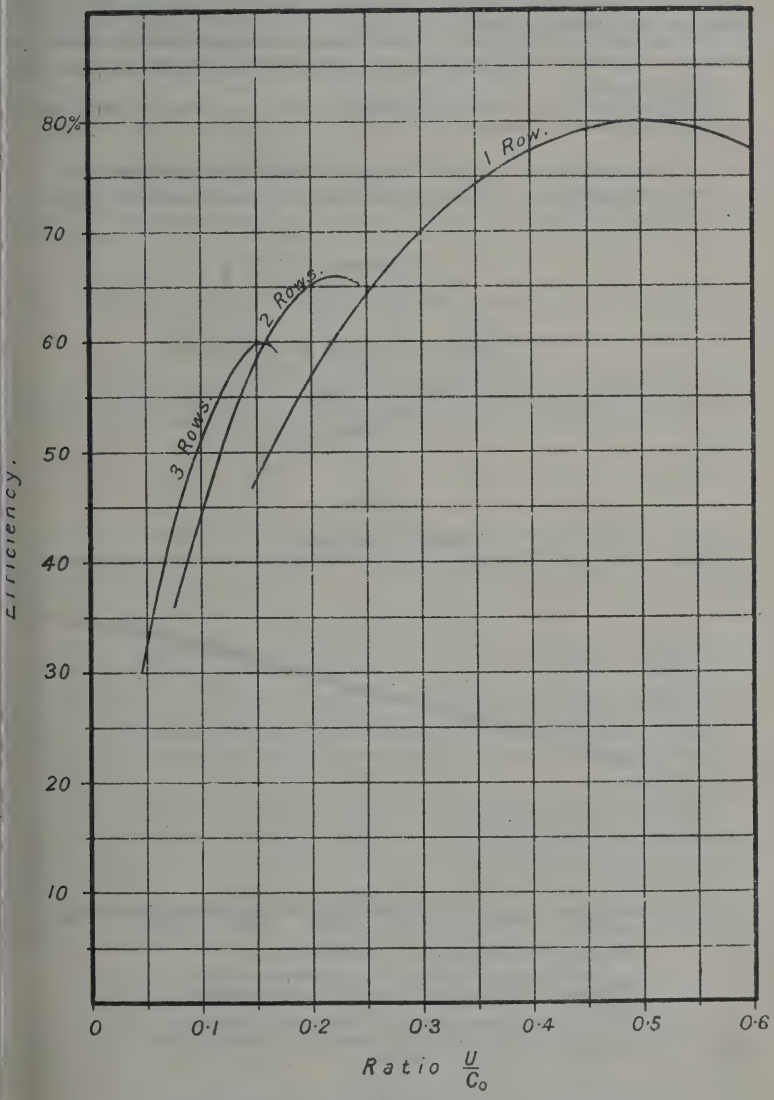

FIG. 8.

CARRY-OVER ENERGY.

In pressure-compounded impulse turbines, the kinetic energy of the steam leaving the last blade of any pressure stage—except the last—is not entirely lost; part of it at least being recovered in the succeeding stage.

The total energy available in the succeeding stage is then greater than the adiabatic heat drop by an amount equal to $\frac{a c^2}{2g}$, where c is the absolute velocity of exit from the velocity blade and a is a constant.

For full admission, Prof. Rateau has suggested the value $a = \frac{2}{3}$, while for partial admission the value $a = \frac{1}{2}$ may be taken.

THE VALUE OF ψ, THE VELOCITY COEFFICIENT FOR BLADES.

The value of ψ has been the subject of researches by Prof. Rateau* and Dr. N. Briling.†

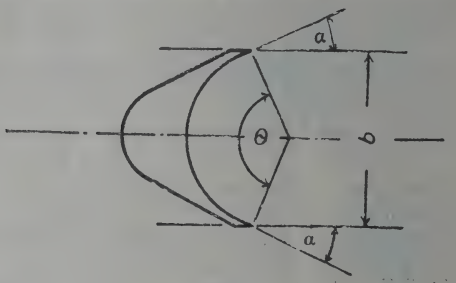

FIG. 9.

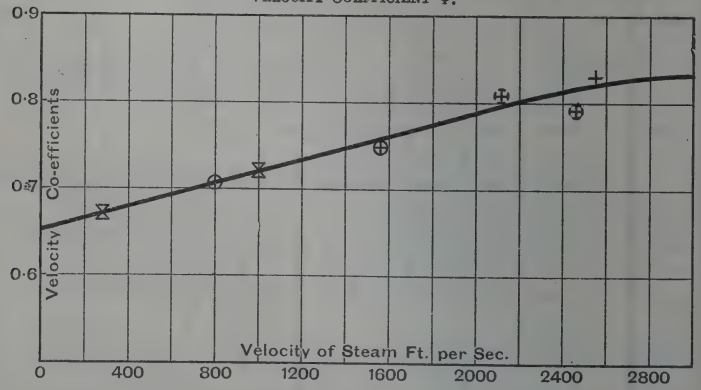

⊕ *Rateau. (Engineering 10/12/09) Mean Values.*

⊕ *Values deduced from Rateau's experiments on Bucket Reaction; Congrès International de Mécanique Appliquée 1900.*

\+ *Stodola "Steam Turbines" deduced from Delaporte's Test of a de Laval Steam Turbine.*

FIG. 10.

* *Engineering*, December 10, 1909. † *Z. Ver. Deutsch. Ing.*, January 1906.

Prof. Rateau found that ψ was a characteristic of each type of blade depending on their size and spacing and slightly increasing with velocity.

Dr. Briling, whose experiments covered a wider field, found that ψ increased with velocity, decreased with the width of the bucket, and appeared to be principally dependent upon the angle through which the steam was diverted in the blade.

Briling deduced the following formula from his experiments:

$$\psi = \psi_o - 0{\cdot}000432\,\theta^{\frac{4}{3}}$$

where θ = total angle in degrees through which steam is turned in the blade (see fig. 9, p. 1838).

ψ_o = 0·90–0·97 for blades with rounded inlet edges.
= 0·95–0·99 for blades with sharp edges.

Mr. H. M. Martin* has given a useful diagram combining Rateau and Briling's results with others deduced from various tests, which is reproduced in fig. 10; from this the following expression can be deduced:

$$\psi = 0{\cdot}65 + \frac{w}{15{,}000}$$

w being the velocity of the steam relatively to the blade in ft. per sec.

PITCH OF IMPULSE BLADES.

The best value of the pitch p has been determined experimentally by Dr. Briling † as being connected with the blade angle $\alpha°$—which he takes as being the same at the inlet and outlet—and the blade width by the following relation:

$$p = \frac{r}{2 \sin \alpha°}$$

$$r = \frac{b}{2 \cos \alpha°}$$

Briling is of the opinion that 30° is the most suitable angle for impulse blading.

In practice, the blade angle varies from 20° to 50°, the largest angles being used at the exhaust end of a turbine when it becomes difficult to provide sufficient area. The pitch varies from 0·5 to 0·75 of the blade width.

REACTION TURBINES.

In a reaction turbine the available heat energy of the steam is converted into kinetic energy both in the stationary and the moving blades.

In the most usual case—*considering a stage as consisting of a fixed blade and the following moving blade*—one-half of the available heat drop per stage is utilised in the fixed blade and the remainder in the moving blade. The turbine is then said to have a half degree of reaction.

Thus, both the fixed and moving blades perform the function of a nozzle in precisely the same way, and are identical in form and thermodynamic purpose.

Since there is a heat drop in the moving blades, there must also be a pressure drop across them. This is a characteristic of the reaction turbine as compared with the impulse turbine.

A second characteristic lies in the fact that the arc of admission to the first stage of a reaction turbine must extend around the complete circumference. For this reason nozzle cutout governing is not possible, and overloads can only be dealt with by admitting steam at some intermediate point in the expansion.

The steam enters the moving blades with a relative velocity approximately in an axial direction, and leaves them at a higher velocity in a direction inclined to the plane of rotation, the blades being impelled forward by the reaction of the leaving steam.

Reaction Blading with Half Degree of Reaction.

In this case since the outlet angles of the fixed and moving blades are the same, and the heat drop utilised in both is the same, the velocity triangles at inlet to and exit from the moving blade are identical (see fig. 11, p. 1840).

* *Steam Turbines—their Theory and Construction*, H. M. Martin.
† *Z. Ver. Deutsch. Ing.*, January 1906.

Hence

$$c_1 = w_1^1 \; ; \; c_1^1 = w_1.$$

If h = heat drop in any stage (one fixed and one moving blade) and with the remaining symbol as were used when considering impulse turbines—

$$c_1 = \frac{1}{2\,U\cos\alpha}\,(25{,}050\,\zeta\,h + U^2);$$

where $(1 - \zeta)$ is the energy loss in the conversion of heat to velocity.

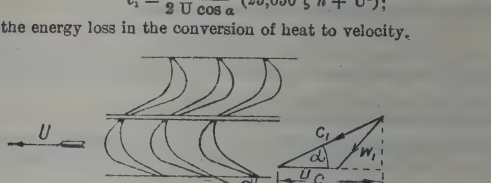

FIG. 11.

Capt. Riall Sankey has given 0·8 as the value of ζ, whereas the statement of Sir Chas. Parson that the blading efficiency in the low-pressure end of the turbines of the 'Mauretania' reache the value of 85 per cent., shows that ζ may be as high as 0·86 under those conditions, while th efficiencies reported to have been obtained with the Ljungström turbine of quite small capacitie could only be reached if ζ was as much as 0·85.

U and α being known, the velocity triangles can be drawn.

The work done per stage

$$= W\,\frac{(c_1^2 - c_1'^2)}{2g}, \text{ or, } = W\,\frac{(2k\cos\alpha - 1)}{g}v^2, \text{ where } k = \frac{c_1}{U}.$$

The blading efficiency

$$\eta_B = \frac{c_1^2 - (c_1'^2)}{2g\,J\,.\,h}, \text{ or, } = U^2\,\frac{(2k\cos\alpha - 1)}{J\,.\,g\;\;h}.$$

The required blade length can be obtained from the relation

$$\pi\,.\,D_m\,.\,l\,.\,q = \frac{W\,.\,v_2}{W_1},$$

where D_m = mean diameter of annulus in feet; l = radial length of annulus in feet = (blad height) + (tip clearance); v_2 = the specific volume after the moving blade in cubic feet per lb. q = annulus area factor.

At any stage the 'annulus area factor' is the ratio of the available area of the channels a exit from the blades in a direction at right angles to α, to the area of the annulus between th drum and the casing at that stage.

The properties of Parsons blading, with the exception of q and α, were published b M. Lelong,* and will be found in Table IV.

As in the case of impulse blading, the blading efficiency varies with $\frac{U}{c_1}$ and reaches a maxi mum when $\frac{U}{c_1} = 0{\cdot}945$ if $d = 19°$, the normal angle for all but the last stages of reaction turbine Under this condition U becomes equal to $c_1 \cos\alpha$. Such a high value is not practicable i ordinary working conditions, nor is it necessary for the realisation of high efficiency, because th curve connecting $\frac{U}{c_1}$ and η_B is very flat in the region of its maximum.

Fig. 12 (p. 1842), which gives this relation for $\zeta = 0{\cdot}8$, is due to Stodola.†

The efficiency for changes of ζ within the limits actually to be met with can be obtained b increasing the efficiency as obtained from fig. 9 by the same percentage as ζ exceeds 0·8.

In electrical work $\frac{U}{c_1}$ varies from 0·5 to 0·8.

The peripheral velocity of forged steel drums may be as high as 400 ft. per second, and eve higher speeds are possible with solid drums, or drums made from special steels of high ultimat strength.

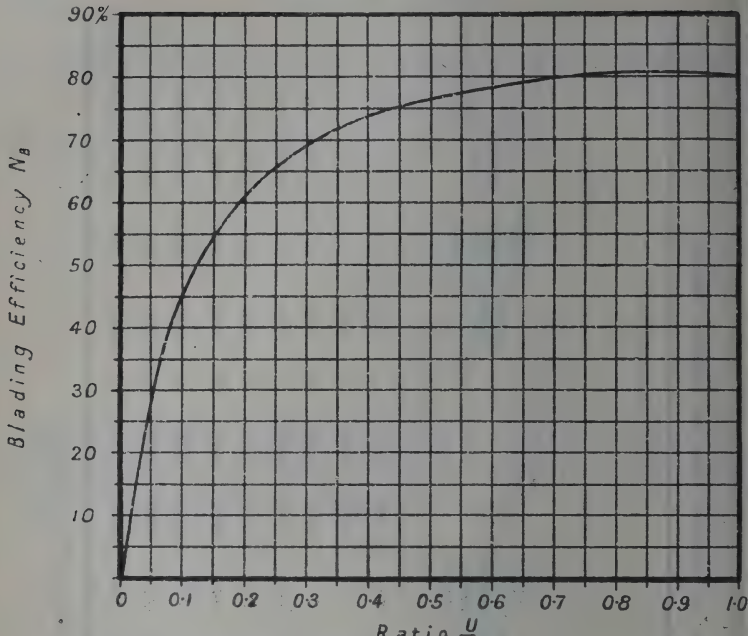
For Double Wing Blades α 60°; $q = 0·85$ in.



EFFICIENCY OF REACTION BLADING FOR $\zeta = 0{\cdot}8$.

FIG. 12.

The velocity of the steam c varies from 300 ft. per second in the initial to 1,000 ft. per second in the final stages.

In marine work $\frac{U}{c_1}$ varies from 0·3 to 0·45, and for the high-pressure stages the peripheral velocity varies from 80 to 120 ft. per second.

REACTION TURBINE DESIGN.

The blades of Parsons turbines are not usually increased in height from row to row, but are arranged in groups having the same height and the same mean diameter. The angles of the blades of any one group are usually the same, but in some cases they are gradually increased so as to obtain the correct progression of areas for constant steam velocity relatively to the blade.

The blades of such turbines for land purposes are generally placed on three-drum diameters of increasing size, referred to as the H.P., I.P. and L.P. expansions.

The relative distribution of heat drop between the different expansions and their relative geometric properties are given in the following table :—

Expansion.	H.P.	I.P.	L.P.	H.P.	I.P.	L.P.
Adiabatic heat drop used . .	1	1	2	1	1	1
Number of groups of blades .	1	1	2	1	1	1
Mean diameter of annulus . .	1	$\sqrt{2}$	2	1	$\sqrt{2}$	2
No. of rows of blades per group .	1	$\frac{1}{2}$	$\frac{1}{4}$	1	$\frac{1}{2}$	$\frac{1}{4}$
No. of rows of blades per expansion	1	$\frac{1}{2}$	$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{4}$

The first of these arrangements is that most commonly adopted.

In electrical work there are from two to three groups of blades in the H.P. expansion.

In any given turbine and for groups of blades with the blade angle the same, the ratio $\frac{D^2 l}{v}$ should be constant, where D = mean diameter of the blades, l = their length, and v = the mean specific volume of the steam in the group.

The last three rings on the L.P. expansion were formerly made the same height, but with increasing discharge angle, the latter corresponding respectively to 'normal,' 'semi-wing' and 'wing.' By this means the final ring (*i.e.* wing blades) has double the discharge area of the ring of 'normal' blades of the same height, but without any increase in the centrifugal stresses. The practicable height ratio of $\frac{\text{blade height}}{\text{rotor diameter}}$ was $\frac{1}{7}$ with blades cut from rolled parallel strip. In modern practice a still larger height ratio ($\frac{1}{4}$) is obtained, with a view to obtaining still larger discharge area in the final ring, by the use of twisted blades which are also, if necessary (on account of centrifugal stresses), tapered from root to tip. In these blades the discharge opening ratio $\frac{o}{p}$ is kept constant from root to tip and equal to about 0·71 (*i.e.* wing), but the discharge angle is progressively varied by twisting. The guide ring is made complementary to the final rotating ring, being twisted, but not tapered.

In order to reduce the unsupported length between bearings, and to enable the tip clearance to be kept small, it is becoming the practice in turbines of 5,000 kw. and over to use two cylinders. The first cylinder contains the H.P. expansion only and can be made of cast steel, very fine clearances being possible by eliminating the danger due to the growth of cast iron.

e_1, for any particular stage, can be calculated from the formula already given when the heat drop h is known.

The blading efficiency throughout the turbine can be found from fig. 12 when the ratio $\frac{U}{e_1}$ is known.

For groups of blades having the same angles and height:

if

n = number of blades in the group considered; R = ratio of expansion over the group; H_a = adiabatic heat drop for the group,

then the heat drop used in the first stage

$$h_1 = \frac{(1+\epsilon)H_a}{\left[0{\cdot}07 + \left(\frac{R^2-1}{R^{\frac{2}{N}}-1}\right)\right]}$$

The heat drops for the other stages of the groups form with h_1 a geometric progression having $R^{\frac{2}{N}}$ as a common ratio.

In most cases it will be sufficient to calculate the first and last stages of any one group.

Disc and Drum Type.

Just as in the development of the pure impulse turbine combinations of the simple types have been evolved, so the disc and drum type has been introduced into the sphere of the reaction turbine.

In this case the high pressure and less efficient part of the reaction turbine is replaced by a Curtis wheel having as a rule two rows of blades. This design possesses the advantages already mentioned in connection with combination impulse turbines, and in addition it results in a considerably shorter and stiffer rotor than in the pure Parsons machine.

TURBINE LOSSES.

Diaphragm Gland Loss.

The diaphragms of a pressure-compounded impulse turbine must obviously be provided with a clearance between themselves and the shaft, thus providing a leakage area through which steam can pass.

The diaphragm gland is usually made either as a labyrinth packing or as a closely fitting white metal bush.

Although the clearances may originally be very small they are greatly increased by whipping of the shaft, or even by the static deflection.

The percentage leakage can be estimated as being equal to the ratio of the clearance area to the nozzle area in any diaphragm.

In order to reduce this loss, some designers employ carbon packings held together by garter springs in the diaphragms.

The diaphragm clearance is usually from $\frac{10}{1000}$ ins. to $\frac{30}{1000}$ ins. radially.

PACKINGS.

Labyrinth Packings.

The glands at the cylinder ends are usually of the labyrinth packing type.

In impulse turbines the labyrinth is invariably of the radial clearance type, while in Parsons turbines the packing at the thrust block end is of the axial clearance type, the other being of the radial clearance type.

Mr. H. M. Martin* has deduced the following formulæ:

$$\text{Weight of leakage steam} = 68 \cdot A \sqrt{\frac{p_o\left(1-\frac{1}{r}\right)}{v_o\,(N + log_e\, r)}} \text{ lbs. per sec.,}$$

where

p_o = pressure before the gland in lbs. per sq. in.; v_o = specific volume of steam in cu. ft. per lb. r = ratio of expansion through gland; N = number of labyrinths; A = sectional area of leakage path in sq. ft.

If the velocity with which the steam flows out of the last labyrinth is greater than sound velocity, this formula should be amended, but the correction is small, and as it is in the nature of a reduction in the weight of the leakage steam, it can safely be neglected where N is greater than 8, which is the usual case in practice.

N varies between wide limits and may be from 8 in the case of low-pressure glands of impulse turbines to 30 for the high-pressure glands of Parsons turbines.

The clearance usually allowed varies from $\frac{10}{1000}$ in. to $\frac{20}{1000}$ in., but this may increase in actual working in the same manner as the diaphragm clearances.

In order to reduce the loss of turbine efficiency due to gland loss, which might otherwise be considerable, the high-pressure packing is usually connected at one or two points in its length to some intermediate stage in the turbine.

The leakage over each of these sections can be calculated by the formulæ already given, r now being the ratio of expansion over any section, and p_o, v_o the conditions before that section.

Except in those cases where a water gland is used, the gland at the exhaust end is sealed by steam at a higher pressure than atmospheric, taken from a stage in the turbine, and in order to ensure that air is not leaking into the exhaust, the pressure is adjusted until a small quantity of steam is seen escaping into the engine-room.

The cylinder glands of the A.E.G., Zoelly, and Curtis turbines are of the carbon type, for which a considerable reduction in leakage is claimed.

The advantages of these are questionable since they cannot be renewed or adjusted without opening the turbine, and in some designs it is even necessary to strip the rotor.

The carbon rings which are in segments are kept together and caused to bear on the shaft by garter springs.

'Britimp' Brand Metallic Packings.†

(*British Metallic Packings Co., Ltd., 7 Princes Street, Westminster, S.W.* 1.)

Each packing of this brand consists of two complete rings of carbon, X, X (fig. 12A). Each ring is in three sections. The outer circumferences of the rings are coned in opposite directions and the coned surfaces are shrouded by a light metal ring Y, which is also in three sections.
